Cutaneous Lesions. Skin and soft-tissue manifestations are rare. Even if echinococcal cysts can implant in soft tissues (in less than 2 percent of infected patients), a recent review of the literature revealed only two cases of patients initially presenting with a soft-tissue mass.[99] Cysts may manifest as firm subcutaneous or intramuscular nodules or masses that are fluctuant and non-tender to palpation (Fig. 207-13). There is no epidermal change. Skin fistulas from a hydatid cyst in a patient known to have an infection with *E. granulosus* have been reported. If the cyst leaks fluid, the patient may have urticaria and manifestations of anaphylaxis secondary to the allergic reaction to foreign antigens from cyst fluid.

Infection with *E. multilocularis* may cause multiple supraumbilical cutaneous and subcutaneous nodules associated with ulceration, surrounding inflammation, and painless cutaneous fistulas. These cutaneous localizations manifestations usually result from the extension of an underlying visceral lesion.[100]

Laboratory Tests. Peripheral eosinophilia is present in only a small percentage of patients with intact cysts. In contrast, leakage of cyst fluid commonly causes eosinophilia.

Special Tests. Identification of the parasite in a cyst confirms the diagnosis. Characteristic morphology of the parasite as seen by imaging (e.g., ultrasound, computed tomography scan, and magnetic resonance imaging) can suggest the diagnosis and can detect clinically silent lesions.

▲ **FIGURE 207-13** Abdominal bulge from intraperitoneal cyst of echinococcosis. (Used with permission from Jay S. Keystone, MD, FRCPC.)

Serologic studies can aid in the diagnosis and may be useful in following patients after surgical treatment.[98]

In *E. granulosus*, serologic tests may be negative, especially in patients with lung lesions. Tests that assess circulating antigen, including molecular techniques using PCR are being developed.

Serologic tests are usually positive at high titers in patients infected with *E. multilocularis*.

Differential Diagnosis. When there is skin involvement, the differential diagnosis includes other cutaneous nodules (see Table 207-4), other cystic lesions of soft tissues and urticaria (see Chap. 37).

Treatment. Isolated cysts caused by *E. granulosus* are often resected. Percutaneous aspiration, injection, and reaspiration with ultrasound guidance is a minimally invasive technique being used increasingly to manage hepatic disease.[101–103] (See also http://whqlibdoc.who.int/hq/2001/WHO_CDS_CSR_APH_2001.6.pdf.) Albendazole may be useful before surgery or in the event that the cysts rupture or leak during surgery. It has also been used in infections that are not resectable.

Surgical resection can be curative in *E. multilocularis* infection if the diagnosis is made early.

Prevention. The incidence of *E. granulosus* infection may be decreased by preventing dogs and other canines from feeding on infected offal.

CYSTICERCOSIS (*TAENIA SOLIUM*)

Synonyms. Larval taeniasis.

Epidemiology. *Taenia solium* is a common parasite in Central and South America, Africa, parts of Asia, and Eastern Europe. In the United States, this disease appears primarily in immigrants from endemic areas where poor sanitation and pig farming are common, although acquisition of infection has been well documented in the United States. Cysticercosis is the most common helminthic infection of the CNS.

Humans acquire cysticercosis by ingesting eggs in food, water, or on fingers contaminated with human feces. Humans infected with adult worms may acquire cysticercosis by ingesting eggs passed in their own feces.

Etiology and Pathogenesis. The larval stage of the pork tapeworm, *T. solium,* causes cysticercosis.[104] In humans, *T. solium* infection causes both intestinal taeniasis and cysticercosis. The human host can have either form of infection alone. Intestinal taeniasis is found in 25 percent to 50 percent of patients with cysticercosis. Intestinal infection with the adult parasites follows eating raw or undercooked pork containing cysticerci. The larval cysts attach to the small bowel mucosa and develop into adult worms. Eggs from the adult worm in human small intestine are passed in feces and may remain viable for weeks.

Clinical Findings. The clinical features range from asymptomatic to fatal.

Cutaneous Lesions. Approximately one-half of patients with cysticercosis present with subcutaneous nodules.[105] The time from infection to the appearance of subcutaneous nodules is highly variable and may be from months to years. Cysticerci can survive in humans for 10 to 15 years. Symptoms may begin or continue long after the parasites are dead. The skin findings include single or multiple firm, mobile, round, well-circumscribed subcutaneous nodules that may

be tender or asymptomatic and that range in size from millimeters to centimeters (usually approximately 2 cm in diameter; see Table 207-4). Common anatomic locations are the extremities and trunk; in a series from Nepal, 10 percent of patients had nodules in the oral mucosa.[106]

Related Physical Findings. Although the CNS (see eFig. 207-13.1 in on-line edition), subcutaneous tissue, skeletal muscle, and eye are the most commonly affected sites, the heart, kidneys, liver, lungs, and pancreas may be involved. Seizures are the most common manifestation of neurocysticercosis. Almost 50 percent of patients with CNS cysticerci found at autopsy had no history of CNS symptoms.

Laboratory Tests. Peripheral eosinophilia is absent most patients (85 percent) with neurocysticercosis. High-grade eosinophilia in a patient with cysticercosis should motivate a search for another process to explain the eosinophilia.

Special Tests. Diagnosis is confirmed by identifying the parasite by its characteristic morphology in a surgically excised cutaneous nodule. Diagnosis of cysticercosis in a subcutaneous nodule should lead to evaluation for possible neurocysticercosis.

Serologic tests are also available.[107] High sensitivity and specificity have been reported with an enzyme-linked immunoelectrotransfer blot assay and with an ELISA. Sensitivity is high in patients with multiple lesions, but one study found that only 28 percent of patients with a single lesion had positive enzyme-linked immunoelectrotransfer blot assay results. Other immunologic tests have been less sensitive and less specific.

Lesions of neurocysticercosis can be seen and their development stages of larval cysts evaluated on MRI. Cerebrospinal fluid may be normal or may contain increased protein and cells, including eosinophils and plasma cells.

Differential Diagnosis. For subcutaneous lesions of cysticercosis, the differential diagnosis includes benign cysts, soft-tissue tumors, and other parasitic causes of nodules (see Table 207-4).

Treatment. (See Box 207-1) The use of anthelmintic drugs for parenchymal cysticercosis remains controversial.[108,109] Decisions about treatment depend on the location and characteristics of the lesions (viability of the cysts) and may include surgery as well as medical therapy with anticonvulsants, steroids, and an anthelmintic drug. Albendazole and praziquantel (considered investigational for this condition by the U.S. Food and Drug Administration) are active in cysticercosis. Because a cysticercocidal drug may cause leakage of antigen from a viable cyst and intense, damaging local inflammatory reaction, careful evaluation for intraocular and CNS lesions should be carried out before any antiparasitic drug is given. Concomitant intestinal taeniasis due to *T. solium,* if present, should be treated to eliminate a potential ongoing source of infection for the patient and contacts.

Prevention. Preventive measures include proper disposal of feces, avoidance of fecal contamination of food and drink, and treatment of intestinal taeniasis.

Other Cestode Infections

COENUROSIS ***Synonyms.*** Disease in sheep is named *gid* and *staggers*.

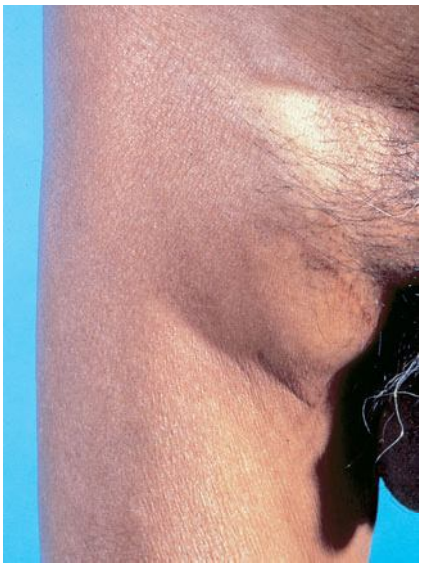
Epidemiology. Reported human cases of coenurosis are sporadic and rare, with the majority from Africa.[110] Infections have occurred in Asia, Europe, and North America, particularly in areas where sheep are common. In tropical Africa, infections are more commonly located in subcutaneous or muscle tissue, or the eye and orbit (particularly in children). In non-tropical Africa, infections occur primarily in the CNS of adults.

Etiology and Pathogenesis. Coenurosis is caused by the larval stages of several species of *Multiceps,* a cestode (tapeworm),[111] most often *M.(Taenia) multiceps, M.(Taenia) serialis,* and *M.(Taenia) brauni*.

SPARGANOSIS ***Synonyms.*** Spirometrosis, sparganum infection.

Epidemiology. The parasite is found in animals on all continents, but most human cases are from China, Japan, and Southeast Asia. Cases have also been reported from Africa, Australia, Caribbean islands, Southern Europe, and the Americas.

Etiology and Pathogenesis. The tapeworm larvae of the genus *Spirometra,* including *S. mansoni, S. erinaceri,* and *S. mansonoides,* cause sparganosis.[112] At least 10 cases have been caused by *S. proliferum*.



▲ **FIGURE 207-14** Soft-tissue swelling of sparganosis. (Used with permission from Jay S. Keystone, MD, FRCPC).

Clinical Findings. The severity of infection depends on the route of infection, the number of parasites, and the anatomic locations involved.[113]

Cutaneous Findings. Sparganosis caused by ingestion of the infective larvae presents as a slow-growing nodule in subcutaneous tissue or in skeletal muscle (occasionally migratory; Fig. 207-14) onset, 20 days to 14 months after ingestion. The lesion may be pruritic and tender or non-tender. The larvae can survive in humans for at least 9 years. Sparganosis due to the local application of infected flesh results in localized pruritus, then erythema, edema, and subcutaneous nodules that are painful on palpation.

CHAPTER 208

Scabies, Other Mites, and Pediculosis

Stephen P. Stone
Jonathan N. Goldfarb
Rocky E. Bacelieri

SCABIES

Epidemiology

Scabies is a human skin infestation caused by the penetration of the obligate human parasitic mite *Sarcoptes scabiei* var. *hominis* into the epidermis. The scabies mite is an arthropod of the order Acarina which was first identified in the 1600s, but was not recognized as the cause of the skin eruption until the 1700s.[1] There are estimates that over 300 million people worldwide are infected with the scabies mite.[2] Scabies affects all socioeconomic classes, with women and children being disproportionately infected. It tends to be more prevalent in urban areas, particularly in overcrowded regions. There is evidence of a seasonal variation, with more cases being diagnosed in the winter months than the summer.[3] The incidence of scabies has been increasing over the past two decades, and has been found to be responsible for major outbreaks in nursing homes, prisons, and hospital wards. Transmission of the mite occurs usually through close personal contact, although the scabies mite can live off the human skin for up to 3 days, and therefore some infections can be from exposure to fomites.[4]

SCABIES AT A GLANCE

- Human infestation caused by *Sarcoptes scabiei* var. *hominis*, an obligate human parasite that lives its entire life cycle in and on the skin.
- Produces a diffuse, pruritic eruption after an initial incubation period of 6 to 8 weeks.
- The pathognomonic clinical feature is a burrow produced by the tunneling of the mite in the stratum corneum.
- Is transmitted by close physical contact, but fomite transmission is possible.
- Topical scabicides are the preferred treatment, although oral ivermectin has been found to be an effective therapy.

Etiology and Pathogenesis

The scabies mite has four pairs of legs and measures 0.3 mm in diameter. It is therefore not easily seen with the naked eye. The mite cannot fly or jump; it lives its entire 30-day life cycle in and on the epidermis. The female mite burrows into the stratum corneum within 20 minutes and lays approximately 3 eggs a day. The eggs hatch after 4 days, and the larvae migrate to the skin surface and mature into adults.[5] After 2 weeks, female and male mites copulate, after which the gravid female burrows back into the stratum corneum. The male, which is slightly smaller than the female, falls off the skin and perishes. The average number of mites a host harbors is usually less than 20, except in "crusted scabies" (previously known as *Norwegian scabies*), in which a host may harbor over a million mites.[5] Individuals with human immunodeficiency virus, the elderly, and patients with medication-induced immunosuppression are at risk of developing crusted scabies, although it has been reported among immunocompetent indigenous Australians.[6]

Clinical Findings

After the initial exposure to the scabies mite, the pruritus and rash may take up to 6 to 8 weeks to develop. Subsequent exposure to the mite results in the itching and the rash developing within a couple days, probably due to prior sensitization to the scabies mite.[7] The itching is severe and usually worst at night. The lesions appear as red, scaly, sometimes crusted (excoriated) papules and nodules that favor the interdigital webs (Fig. 208-1), sides of the fingers, volar aspects of the wrists and lateral palms (Fig. 208-2), elbows, axillae, scrotum,

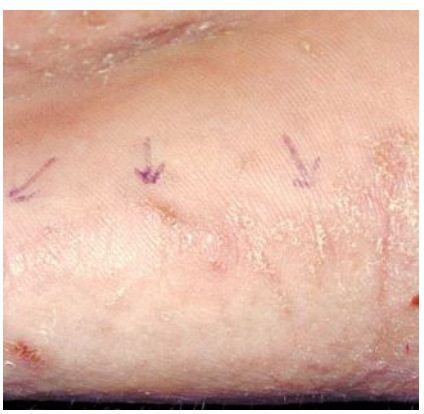
▲ **FIGURE 208-1** Scabies. Several thread-like burrows are present in the web spaces of the fingers and on the knuckles, a common location for these lesions in scabies. Longitudinal scraping of a burrow will often reveal the mite or mite products under microscopic examination.

penis (Fig. 208-3), labia, and the areolae in women. A diffuse erythematous eruption on the trunk may be present and represents a hypersensitivity reaction to mite antigen. The pathognomonic lesion is a burrow, which is a thin, thread-like, linear structure (see Fig. 208-1) that is 1 to 10 mm in length, and is a tunnel caused by the movement of the mite in the stratum corneum. The burrow is best seen in the interdigital webs, wrists, or elbows. However, it can be difficult to find in early cases of the condition, or after the patient has extensively excoriated the lesions. Identification of a burrow can be facilitated by rubbing a black felt-tip marker across an affected area. After the excess ink is wiped away with an alcohol pad, the burrow appears darker than the surrounding skin due to ink accumulation in the burrow.[8]

In infants younger than the age of 2 years, the face and scalp can be infested, whereas in adults this is rarely the case. Erythematous to violaceous pruritic nodules found in the axillae and flanks of the trunk are not an unusual finding in children and on the scrotum in men (see Fig. 208-3), and are thought to be a hypersensitivity reaction to the mite. These nodules can remain for many weeks after the successful eradication of the mite infection. Vesicles and bullae may develop, particularly on the palms and fingers (see eFig. 208-3.1 in on-line edition).

In crusted scabies (Fig. 208-4), hyperkeratotic plaques develop diffusely on the palmar and plantar regions, with thickening and dystrophy of the toenails and fingernails. The rest of the skin usually appears diffusely xerotic. Pruritus is variable and may be totally absent in this form of the disease. Over a million mites populate the skin and these highly contagious patients can be the source of outbreaks in health care facilities.

The definitive diagnosis is made by the microscopic identification of the scabies mites, eggs, or fecal pellets (scybala). This is accomplished by placing a drop of mineral oil over a burrow and then scraping longitudinally with a number 15 scalpel blade along the length of the burrow, being careful not to cause bleeding. The scrapings are then applied to a glass slide and examined under low power (Fig. 208-5). Other diagnostic methods include dermoscopy (see Chap. 5) which can be used to examine the mite in vivo.[10] A polymerase chain reaction–based method has been described in which the DNA from the mite was detected from cutaneous scales.[11] A skin biopsy can be diagnostic, when the scabies mite is found transected in the stratum corneum (see eFig. 208-5.1 in on-line edition).



▲ **FIGURE 208-2** Scabies. Several, slightly scaling, thread-like burrows are seen on the lateral aspect of the palm, associated with a more generalized eczematous process.

▲ **FIGURE 208-3** Scabies: Scabies frequently produces very pruritic, red papules in the genital region. In males, the prepuce is often the site of these lesions.

Differential Diagnosis (Box 208-1)

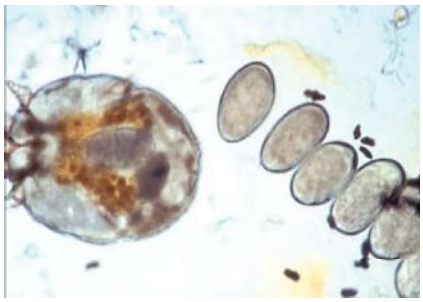
Complications

Secondary impetiginization is a common complication and usually responds well to either topical or oral antibiotics, depending upon the extent of the pyoderma. However, lymphangitis and septicemia can develop, particularly in crusted scabies (see eFig. 208-5.2 in on-line edition). Post-streptococcal glomerulonephritis has resulted from scabies-induced pyodermas caused by *Streptococcus pyogenes*.[12]

Prognosis and Clinical Course

If left untreated, the condition can persist for many years. In immunocompe-

▲ **FIGURE 208-4** Crusted scabies. Hyperkeratotic plaques populated with thousands of mites.



▲ **FIGURE 208-5** Scabies. Microscopic examination of a mineral oil preparation after scraping a burrow reveals a gravid female mite with oval, gray eggs and fecal pellets.

tent individuals, the number of mites may decrease over time.

Treatment

There are a number of treatments for scabies which have various levels of effectiveness. Factors which may determine which treatment to use are the age of the patient, the cost of the medication, the severity of the eruption, and if previous treatments have been unsuccessful.

In adults, topical scabicides should be applied to the entire skin surface, excepting the face and scalp, with special attention to the intertriginous areas, the genitalia, the periungual regions, and behind the ears. In children and those patients with crusted scabies, the face and scalp should also be treated. Patients must be informed that even after adequate scabicidal therapy, the rash and pruritus may persist for up to 4 weeks; otherwise they may believe that the prescribed treatment was unsuccessful, and then inappropriately overuse scabicidal medications. Topical steroids, antihistamines and, if necessary, a short course of systemic steroids, can be prescribed to alleviate the pruritus and rash once the patient has completed the scabicide treatment. The treatment of scabies is summarized in Box 208-2.

Box 208-1

Differential Diagnosis of Scabies

Most Likely

- Atopic dermatitis
- Insect bite reactions
- Contact dermatitis
- Dermatitis herpetiformis
- Dyshidrotic eczema

Consider

- Psoriasis, particularly in the crusted variety
- Bullous pemphigoid, when vesicles and bullae are present
- Drug eruption

The only oral but highly effective scabicide known to date is ivermectin. It was discovered in the 1970s in the fermentation broth of a soil actinomycete *Streptomyces avermitilis*. It is structurally similar to macrolidic antibiotics, but with no antibacterial activity.[16] It is currently U.S. Food and Drug Administration (FDA) approved for the treatment of the intestinal stage of onchocerciasis and strongyloides, but not FDA approved for the treatment of scabies. Its activity against the scabies mite is due to its high affinity for the gluminated-gated chloride ions found in the peripheral nervous systems of invertebrates.[17] Ivermectin blocks the channel transmission across the nerve synapse that uses γ-aminobutyric acid. This results in the paralysis and death of invertebrate parasites. In mammals, these receptors are confined to the central nervous system and in normal conditions the drug does not cross the blood-brain barrier. It has been suggested that conditions that disrupt the blood-brain barrier may allow the drug to enter the central nervous system.[18] Therefore the drug should not be used in children younger than the age of 5 years or weighing less than 15 kg, or during pregnancy or lactation, although there are reports of ivermectin being used in young children and during pregnancy without adverse effects.[19]

There are been numerous reports of the effectiveness of ivermectin in the treatment in scabies.[20] The usual dosage is 200 μg/kg; often the dose is repeated in 10 to 14 days, but the optimal dosage schedule for the treatment of scabies has not been established. A clinical study comparing ivermectin to topical 5 percent permethrin revealed that a single dose of ivermectin provided a cure rate of 70 percent, which was increased to 95 percent with a second dose 2 weeks later. A single application of permethrin was curative in nearly 98 percent of patients.[21] A topical preparation of 1 percent ivermectin has been shown to be effective in early clinical studies, but is not yet commercially available.[22] In crusted scabies, the combination of ivermectin and a topical anti-scabicide is often used due to the severity of the infection, and multiple courses may need to be used to eliminate the infection.

Side effects of ivermectin are usually mild and transient; however, there have been reported rare side effects of hypotension, laryngeal edema, and encephalopathy.[23] There is one case report of an increased death rate in elderly nursing home patients who were treated with ivermectin.[24] Subsequent studies have not confirmed this finding.

Prevention

Individuals in close contact with the infected person should be treated with a topical scabicide. Treatment should be directed to prevent spread of the scabies, because individuals may be harboring the scabies mite during the asymptomatic incubation period. Additionally, to prevent re-infection with fomites, bed sheets, pillow cases, towels, and clothes worn during the past 5 days should be washed and dried in the hot cycle, or be

Box 208-2

Treatment for Scabies

DRUG	DOSE	COMMENTS
Permethrin 5% cream	Applied for 8–14 h; often repeated in 7 days.	First-line treatment in the United States; pregnancy category B
Lindane 1% lotion	Applied for 8 h then washed off. Second application recommended after 1 wk.	Not recommended for children under 2, during pregnancy, or lactation; resistance has been increasing; banned in California
Crotamiton 10% cream	Applied on 2 consecutive days; repeated once within 5 days.	Antipruritic qualities; may not be as effective as other topicals
Precipitated sulfur 5%–10%	Applied for 3 days and then washed off.	Safe in children under 2 mo and during pregnancy, but messy to apply and limited efficacy data
Benzyl benzoate 10% lotion	Applied for 24 h then washed off.	Not available in United States
Ivermectin, 200 μg/kg	Single oral dose, can be repeated in 10–14 days.	Highly effective with a good safety profile; can be used along with topical agents, particularly in crusted or resistant cases

dry cleaned. Because the mite can live up to 3 days off of skin, carpets and upholstery should be vacuumed. Pets do not need to be treated because they do not harbor the human scabies mite.

OTHER MITES

Although the scabies mite is the best known mite to infest humans, other mites have been reported to cause disease as well. Mites belong to the class Arachnida, order Acarina [which also includes ticks (see Chap. 210)], and along with the scabies mite are eight-legged organisms, typically with a fused cephalothorax.

Most of the mites of significance to humans fall into three suborders: trombidiformes, mesostigmata, and sarcoptiformes. They tend to be classified according their natural host or habitat (Table 208-1).

Follicle Mites

Demodex sp. are common residents in the human pilosebaceous unit. The mites are found in follicles on the face, scalp, and upper chest. *D. folliculorum hominis* lives within the hair follicle, and *D. brevis* prefers the infundibulum of the sebaceous gland. The prevalence of infestation with *Demodex* sp. increases with age.[25] Infestation is usually unnoticed, but when the mites are present in unusually large numbers, they may play a role in suppurative or granulomatous skin reactions resembling suppurative folliculitis, rosacea, or perioral dermatitis (see Chap. 79).[26,27]

Food Mites

Several species of mites infest stored foods and other organic materials. The most common food mites are the grain mite (*Acarus siro*), the cheese mite (*Tyrolichus casei*), and the mold mite (*Tyrophagus putrescentiae*). All are barely visible, usually less than 0.5 mm long, and more or less translucent with darker mouthparts and appendages. Prolonged contact with mite-infested foods may produce a mild dermatitis known as *baker's itch* or *grocer's itch*, or cause asthma and dust allergies.[28] They do not bite humans.

Straw Itch Mites

Straw itch mites, *Pyemotes ventricosus* and *P. tritici*, can cause epidemics of dermatitis during harvesting and post-harvesting operations in straw, hay, or certain grains. Bites produce a rash-like dermatitis, extending over much of the body and accompanied by itching, sweating, fever, headache, and even vomiting in severe cases. They are beneficial because they feed on larvae of wheat jointworm, rice and granary weevils, Angoumois grain moths, and other pests.[28]

TABLE 208-1
Mites

Type of Mite	Scientific Name	Clinical Features—Disease Associations
Scabies mites	*Sarcoptes scabei*	See the section Scabies
Follicle mites	*Demodex folliculorum hominis* and *D. brevis*	Questionable association with rosacea, idiopathic facial burning
Food mites	Grain mite: *Acarus siro* Cheese mite: *Tyrolichus casei* Grocery mite: *Tyrophagus putrescentiae*	Mild dermatitis known as *baker's itch* or *grocer's itch*
Fowl mites	*Dermanyssus gallinae* and *D. avium*	Pruritic papules, sometimes with a hemorrhagic center
Straw itch mites	*Pyemotes tritici* and *P. ventricosus*	Patchy dermatitis on trunk and arms during or after harvesting
Harvest or red mites (chiggers)	Genus *Trombicula* *Eurotrombicula alfreddugesi* and *E. splendidus* most common in United States	Scrub typhus vector (*Leptotrombidium* sp.) Papular to vesicular lesion found on ankles, waist, or warm skinfolds
Animal mites	*Ornithonyssus bacoti* *Liponyssoides sanguineus* *Cheyletiella* "walking dandruff"	Endemic/murine typhus vector Rickettsialpox vector Non-specific, pruritic eruption on body parts in close contact with infested pets
House dust mites	*Dermatophagoides* sp.	Questionable association with atopic dermatitis

OTHER MITES AT A GLANCE

- Most mites (exceptions: scabies and *Demodex*) drop off the human host after feeding.
- Symptoms generally are due to immunologic reactions.
- Some species are vectors of human disease.

Harvest Mites

There are several mite species belonging to the genus *Trombicula* that may annoy humans directly, especially during the late summer and autumn. The minute, reddish larvae of *Trombicula*, which are less than 0.5 mm long, suck the lymph and blood of humans and other mammals, are often referred to as *chiggers*. *Eurotrombicula alfreddugesi* and *E. splendidus* are seen in the United States. Other species of the genus *Neotrombicula* have been identified as causing dermatitis in humans, and *Leptotrombidium* sp. have been reported to be the vectors for *Rickettsia tsutsugamushi*, the cause of scrub typhus (see Chap. 199).

In the United States, the mites are found in the southern states, in such areas as berry patches, tall grass and weeds, and woodland edges. The larvae feed on humans around the waist, the ankles, or in warm skinfolds, but intense itching usually occurs several hours after the chiggers feed, so they may no longer be present. They can sometimes be seen in the center of an erythematous macule or papule that has not been scratched. Lesions may be vesicular, papular urticaria-like, or granulomatous. An acute seasonal hypersensitivity reaction of the penis has been reported, with edema of glans and foreskin lasting up to 18 days.[29] Treatment is symptomatic, and antihistamines and corticosteroid creams or lotions may be helpful.

Dust Mites

Dust mites are tiny, translucent mites, generally less than 0.2 mm long, and more or less invisible to the naked eye. They feed on the shed skin and other organic debris which constitutes much of the "dust" that settles and accumulates in houses and workplaces. The mites are harmless, but their bodies and

excreta are believed to play a role in severe asthma and other allergic complaints in humans, and delayed hypersensitivity to the mite is felt by some to play a role in atopic dermatitis.[29] Thorough and frequent vacuuming, including bedding and mattresses, can effectively reduce mite infestations.

Fowl Mites

Avian mite dermatitis is infrequently diagnosed in office workers, homemakers, poultry workers, and bird fanciers. It usually can be traced to contact with chickens and pigeons (the latter often nesting in window air conditioners) but has also been attributed to many other avian species (including parakeets) and even gerbils. *Dermanyssus gallinae* and *D. avium* are the most common fowl ectoparasites in the United States, and only temporarily infest humans. Avian mites are blood suckers and have been described as "nocturnal marauders" that "bite and run." The most common manifestations are pruritic papules, sometimes with a hemorrhagic center, located in exposed surfaces, but vesicles, papular urticaria, and dermatitis also have been described.[29]

Animal Mites

The tropical rat mite *Ornithonyssus bacoti* feeds on humans even when rats are present, causing painful bites, intense itching, and dermatitis. They are the vector for endemic/murine typhus. Barely visible, they are bright red to black with white markings and are usually noticed on walls in basements, kitchens, bathrooms, and where rats are found. Mites drop from their host after each blood meal and can survive several days without feeding.[29] The house mouse mite, *Liponyssoides sanguineus*, classically found on mice, can wander away from mice onto walls. It can serve as the vector for rickettsialpox (see Chap. 199).

Cheyletiella sp. are common mites on dogs and cats, and have been described as *walking dandruff*. The mites are highly contagious and there are numerous reports of skin disease in humans; in households with infested animals, as many as 20 percent of their owners are also infested. The mites are not usually found in humans because they do not burrow or reproduce on this host. This has been described as *bite and run* behavior. Lesions such as pruritic, erythematous papules or papulovesicles, urticaria or vesicobullae or excoriated erosions are found on forearms, breast, and abdomen and other areas that have been in close contact with the infested pet.

The pet may be symptomatic or may show evidence of pruritus. An almost pathognomonic sign is dorsal seborrhea sicca (dry white scales) or crusted annular lesions. Diagnosis depends on identifying mites or eggs from the skin, obtained by collecting them with cellophane tape, and examining the scales under the microscope. Treatment of the pet by a veterinarian will clear the pet and its owner(s).[30]

Canine sarcoptic mange (*Sarcoptes scabei* var. *canis*) and feline mange (*Notoedres cati*) may afflict humans with a pruritic dermatosis with excoriation and crusting. Treating the pet clears the humans as well.

PEDICULOSIS

Pediculosis Capitis (Head Lice)

EPIDEMIOLOGY The head and body lice may be variants within a single species, but are thought by most biologists to represent two distinct species that can hybridize or interbreed under special circumstances. The most correct terminology at this time is *Pediculus humanus* var. *humanus* (body louse) and *P. humanus* var. *capitis* (head louse).[31] Head lice infestations occur worldwide and are most common in school-aged children. Previous reports have estimated from 6 million to 12 million infestations occur each year in the United States among children 3 to 12 years of age, although this may be a gross underestimation given that many patients self-treat without reporting to health officials. The lice are spread by close physical contact as well as by the sharing of head gear, combs, brushes, and pillows. Head lice affect all levels of society and all ethnic groups, although in the United States, the incidence is low among African Americans.[32,33]

ETIOLOGY AND PATHOGENESIS The adult louse is 1 to 2 mm long, elongated, flattened dorsoventrally, and wingless. Head lice have three pairs of clawed legs that have been adapted to grasp hairs and can travel up to 23 cm per minute.[31] The louse larva, called a *nymph* or *instar*, looks like a miniature adult louse. An adult louse must take a blood meal before copulation. A female louse can produce 5 to 10 eggs a day during her life span of 30 days. Lice typically survive only 1 to 2 days away from the scalp although under favorable conditions survival up to four days away from the scalp has been reported.[31] Nits can survive for up to ten days away from the scalp.[34]

PEDICULOSIS CAPITIS AT A GLANCE

- Infestations occur worldwide affecting all levels of society and all ethnic groups. In the United States, most commonly in school-aged children.
- Most common complaint is pruritus.
- Most common diagnostic sign is live nits on the proximal hair shaft.
- Spread by close physical contact and sharing of head gear, combs, brushes, and pillows.
- Topical pediculicides remain treatment of choice, although evidence of resistance continues to increase.

CLINICAL FINDINGS Pediculosis capitis is typically confined to the scalp with nits (Fig. 208-6) most often found in the occipital and retroauricular regions. Although patients can be asymptomatic, the most common symptom is itching and the sight of school children scratching their heads often leads to the diagno-

▲ **FIGURE 208-6** Nit sheath. Microscopic view of an egg, containing an unhatched louse, attached to a hair shaft.

Box 208-3

Differential Diagnosis of Head Lice

Most Likely

- Seborrheic scales
- Artifacts on the hair (e.g., hair spray)
- Hair casts (pseudonits)
  - Occur when soft inner root sheath keratin fails to break away from the hair shaft forming a soft ring that encircles hair shaft
  - In contrast to nits, are freely movable along hair shaft

Consider

- White piedra
  - *Trichosporon cutaneum*
- Black piedra
  - *Piedraia hortae*
- Delusions of parasitosis

sis. Pruritus is believed to be the result of a hypersensitivity reaction to the saliva produced by the louse during feeding. Fecal material from the louse is also thought to contribute. There may occasionally be a tiny hemorrhagic crust at the site to indicate the louse has taken its blood meal. In addition to pruritus there are excoriations and lymphadenopathy; conjunctivitis may be observed.[35]

Live nits are placed in close proximity to the scalp because the egg is reliant on warmth and moisture for incubation. Thus the distance of the nit from the scalp along the hair shaft is evidence of the duration of the infestation. When all of the nits are noted to be a significant distance from the scalp (i.e., more than 1 cm), it is likely that the infection is no longer active and that these nits are not fertile. Finding live adult lice, immature nymphs, and/or viable-appearing eggs confirms the diagnosis. Fine combing hair that has been saturated with water and conditioner appears to yield more positive results and fewer false positives than traditional scalp examination.[36,37]

DIFFERENTIAL DIAGNOSIS (Box 208-3)

COMPLICATIONS Secondary bacterial infections may result, primarily due to excoriation.

PROGNOSIS AND CLINICAL COURSE Untreated, head louse infestations may persist for many years.

TREATMENT Pediculicides remain the most effective treatment for head lice. In general, pediculicides should not be used in children less than 2 years. To account for variable ovicidal activity and lack of full patient compliance, it is reasonable to recommend repeating treatment in 7 to 10 days to kill recently hatched nymphs (Box 208-4).[31]

Wet combing involves combing systematically through wet, well-conditioned hair with a fine toothed comb every 3 to 4 days for a total of 2 weeks. Because lice are temporarily immobilized by water, wetting the hair allows easier removal by combing.

Occlusive or suffocation methods, such as petroleum jelly or mayonnaise, have been used in the treatment of head lice for years. Although previous studies have failed to demonstrate an effective cure rate,[48] newer agents [Cetaphil cleanser (initially labeled as Nuvo lotion)] have shown promise.[49,50] In addition, new evidence indicates the nit sheath is composed of proteinaceous compounds instead of chitin-specific compounds, as was previously thought. With this knowledge attention has been turned toward agents that can effectively coat lice and eggs while either preventing formation or leading to degradation of the nit sheath.[51]

Oral agents offer the potential benefit of direct ingestion by the louse during blood meals. This in theory reduces the need for widespread application of chemical substances to promote absorption by the lice and therefore reduces risk of toxicity. Ivermectin has demonstrated systemic activity against head lice and should be considered as an alternative therapy (see Box 208-4).[52]

FAILURE AND RESISTANCE The only definite evidence of treatment failure is the presence of adult organisms. Treatment failure should be suspected if live lice are still present 12 to 24 hours after treatment. Possible contributors to treatment failure include changes in formulations, dilution of the pediculicide to an ineffective concentration when applied to wet hair, application of subtheraputic doses or duration in an attempt to conserve, or re-infestation from untreated contacts.[53]

Drug resistance has garnered much attention in recent years. Although treatment failure may contribute to resistance, examination of resistant populations has revealed the role of several different mechanisms. Mutations associated with knock down resistance are believed to affect highly conserved repeated domains in the sodium channel gene leading to permethrin-resistance.[54] Other mecha-

Box 208-4

Treatment for Head Lice

TREATMENT	MECHANISM OF ACTION	ADMINISTRATION	RISK FACTORS
Pyrethrins, synergized (RID, A-200, R&C shampoo, Pronto, and Clear Lice System)[a]	Block Na^+ channel repolarization[b]	Topically 10 min[c,d]	Allergy to chrysanthemums, ragweed, or related plants
Pyrethrins, synthetic [permethrin 1% (Nix), 5% (Elimite)]	Block Na^+ channel repolarization[b]	Topically 10 min[c,d]	None
Malathion lotion 0.5% (Ovide)	Organophosphate cholinesterase inhibitor[b]	Topically 8–12 h; 20–30 min shown as effective[c]	Highly flammable; respiratory depression; central nervous system toxicity
Lindane shampoo 1% (γ-benzene hexachloride, Kwell)	Organochloride; acts as GABA inhibitor[b]	Topically 5–10 min[c]; due to risk of toxicity do not repeat application. FDA approval as second-line agent only.	Risk of seizures; caution in young children, elderly and patients < 50 kg
Ivermectin, oral	Inhibits GABA release[b]	250 μg/kg dose given 7–10 days apart	Not recommended for patients < 15 kg; caution in pregnancy and breast-feeding

FDA = U.S. Food and Drug Administration; GABA = γ-aminobutyric acid.
[a]Available over the counter.
[b]Produce respiratory paralysis.
[c]Application to dry hair followed by adequate rinse with non-medicated shampoo.
[d]Nits can be removed with comb commonly supplied with product.

nisms identified include glutathione-S-transferase–based resistance (a cause of dichlorodiphenyltrichloroethane and pyrethroid resistance) and monooxygenase-based resistance (enhanced drug metabolism that may be overcome by synergistic agents such as piperonyl butoxide). Resistance patterns appear to follow patterns of drug use explaining the variation in resistance observed across different geographic regions. Treatment should be tailored to local resistance patterns and availability of agents. Future directions in treatment hope to use knowledge of the aforementioned mechanisms in the development of alternate agents or combination of agents.[31.]

PREVENTION All members of the affected household should be examined. Although some physicians recommend treating all household members, others recommend treating affected individuals only. After therapy, the treated individuals should wear clean clothing, and both clothing and bedding should be washed and dried using the hot cycle; nonwashables should be dry cleaned, ironed, put in the clothes dryer without washing, or stored in a sealed plastic bag in a warm area for 2 weeks. Combs and brushes may be washed in very hot water (such as the dishwasher) and may be coated with the pediculicide first, for 10 or 15 minutes. Floors, play areas, and furniture should be carefully vacuumed to remove any hairs with viable eggs attached. Fumigation of living spaces is of no value. "No nit" policies requiring exclusion from school and treatment for all children with nits alone are likely excessive.[55,56]

Pediculosis Corporis (Body Lice)

PEDICULOSIS CORPORIS AT A GLANCE

- Infestations typically observed in groups living in crowded unsanitary conditions, such as the homeless, refugees, and military during wartime.
- Diagnosis made by closely examining the lining of the clothing, particularly the seams, for the presence of nits.
- Pruritus is the most common complaint.
- May act as vectors for *Rickettsia prowazekii* (epidemic typhus), *Bartonella quintana* (trench fever and endocarditis), and *Borrelia recurrentis* (relapsing fever).
- Bathing, discarding, or laundering infested clothing, and restoring proper hygiene should cure infestation.

EPIDEMIOLOGY Pediculosis corporis is a disease of poverty, found almost exclusively among the indigent, the homeless, and groups living in crowded unsanitary conditions, such as refugees and, in wartime, the military—these patients are seen mainly in urban public hospitals. There is no predilection of body lice for race, age, or sex.

ETIOLOGY AND PATHOGENESIS The body louse or *P. humanus* var. *humanus* is approximately 30 percent larger than the head louse, but has essentially the same morphology. The lifespan of the body louse averages 18 days and during this time the female louse can produce 270 to 300 ova. The infestation is usually transmitted by contaminated clothing or bedding. The body louse can survive in the seams of clothing without a blood meal for up to 3 days. After exposure, the inability to wash or change clothes allows the infestation to persist.

CLINICAL FINDINGS Occasionally, a *macula cerulea* (literally, sky-blue spot), a blue to slightly slate-colored macule, can be seen, particularly in areas where clothing binds, such as the waistband, and on the buttocks and thighs (see eFig. 208-6.1 in on-line edition). It is an asymptomatic to slightly pruritic, somewhat bruise-like lesion, up to approximately 1.5 cm in diameter and often with a central punctum. More commonly, the only sign of body lice is excoriations, often linear and primarily on the trunk. Post-inflammatory pigmentation is seen in more chronic cases. Adult lice are rarely seen except in heavy infestations.

Diagnosis is made by closely examining the lining of the clothing, particularly at the seams, for the presence of nits. The clothing may also be shaken out over a sheet of newsprint, at which time the lice may be seen moving about on the paper.

DIFFERENTIAL DIAGNOSIS (Box 208-5)

COMPLICATIONS Excoriation may lead to secondary infection with *S. aureus, S. pyogenes,* and other bacteria. Worldwide, body lice may act as vectors for *R. prowazekii* and *Bartonella quintana* (typhus and trench fevers) and *Borrelia recurrentis* (relapsing fever). In the setting of the urban poor, the body louse most commonly serves as a vector for *B. quintana* that can cause fever or endocarditis.[31] Transmission occurs when contaminated fecal pellets are scratched into the bite site or excoriated skin.

Box 208-5

Differential Diagnosis of Body Lice

Most Likely
- Widespread infestation
- Scabies infestation

Consider
- Early infestation
- Atopic dermatitis
- Allergic contact dermatitis
- Irritant contact dermatitis
- Drug reaction
- Viral exanthema
- Systemic causes of pruritus
- Renal impairment
- Hepatic impairment

Always Rule Out
- Scabies infestation

PROGNOSIS AND CLINICAL COURSE Untreated, pediculosis corporis may persist for many years.

TREATMENT Because lice reproduce in the clothing and not on the skin, bathing, discarding or laundering infested clothing, and restoring proper hygiene should cure the infestation. Bedding should also be laundered with hot water, boiled, or discarded. Woolens and other nonwashables may be dry cleaned or ironed at home, with special attention given to the seams. Some physicians believe that, after appropriate disposition of clothing, the patient should be treated from head to toe with a single application of permethrin 5 percent cream, left on for 8 to 10 hours and then washed off thoroughly.[57]

PREVENTION Treating clothing with a permethrin based tick repellent may help to prevent infestations.[31]

Pediculosis Pubis (Pubic Lice)

EPIDEMIOLOGY Most often pubic lice are a sexually transmitted disease and approximately 30 percent of patients have another concurrent sexually transmitted disease.[58] Fomite transmission has also been documented to occur from contaminated clothing, towels, or bedding.[57]

ETIOLOGY AND PATHOGENESIS Pubic lice or *Pthirus pubis* belongs to a separate genus and species in the family Pthiridae. The

PEDICULOSIS PUBIS

AT A GLANCE

- Commonly spread as sexually transmitted disease or from direct contact.
- Although typically found in pubic hair, can affect any hair-bearing region.
- Pruritus is the most common complaint.
- Diagnosis confirmed by microscopic examination of the plucked hair to identify nits.
- Therapy, similar to pediculosis capitis, targeted to the pubic and perianal regions and adjacent hairy areas.

common term *crab louse* is an excellent description for the distinct morphology, the body being somewhat rounded like that of a crab. Pubic lice range from 0.8 to 1.2 mm in length. With the use of serrated edges on the first claw, pubic lice are able to ambulate up to 10 cm/day. As suggested by its name, this louse is most commonly found in the pubic hair, although in hirsute individuals the short hairs of the thighs, trunk, and perianal area may also be involved. Occasionally, the beard, moustache, and even eyelashes (Fig. 208-7) may be involved. Infestation of the eyelashes and periphery of the scalp occur mainly in children, probably a result of contact with an infested parent. Meinking and Taplin[62] reported as much as 60 percent of a homeless population had crab lice in areas of the body besides the pubic hair. The crab louse has a lifespan of 2 weeks and during this time the female

▲ **FIGURE 208-8** Maculae ceruleae, slate-gray to blue-gray macules, seen on the buttocks.

louse can produce around 25 ova.[31] The adult crab louse can survive away from the human host for up to 36 hours.[59]

CLINICAL FINDINGS As with all pediculoses, patients typically present with pruritus. *Maculae coeruleae* (sky-blue macules), most commonly found on thighs or trunk, may be present as in pediculosis corporis (Fig. 208-8). The diagnosis is most frequently made by the patient him- or herself, often identifying the louse in the pubic area. Infested patients reportedly have an average of 10 to 25 or more adult organisms on the body. When the lice themselves cannot be found, nits may be identified near the base of the hair (Fig. 208-9). As in pediculosis capitis, the duration of infestation can be approximated by the distance of the nit from the skin surface. The diagnosis is confirmed by microscopic examination of the plucked hair to identify the nits. Empty nits may indicate a prior infestation.

DIFFERENTIAL DIAGNOSIS (Box 208-6)

COMPLICATIONS Secondary infection because of excoriation can lead to local lymphadenitis and fever.

▲ **FIGURE 208-9** Pediculosis pubis. Several lice and their dot-like nits attached to the hair shafts can be seen in the pubic area of this patient. (Used with permission from D.A. Burns, MD.)

PROGNOSIS AND CLINICAL COURSE Untreated, pediculosis pubis infestations may persist for years.

TREATMENT Topical therapy is much the same as that for pediculosis capitis. The preparation should be applied to the infested area, paying particular attention to the pubic and perianal regions and adjacent hairy areas. A common cause of failure is treating only the pubic area in hairy individuals: The pediculicide should be applied to the thighs, trunk, and axillary regions because the mite can infest these areas as well. Sexual contacts should be treated simulta-

◀ **FIGURE 208-7** Pediculosis pubis. Eyelash infestation with *Pthirus pubis*. Nits can be seen attached to the eyelashes. (Used with permission from D.A. Burns, MD.)

Treatment for Pubic Lice

TREATMENT	ADMINISTRATION	COMMENTS
Synergized pyrethrins and permethrin 1% shampoos	Topically 10 min; repeat in 7–10 days	Available over-the-counter
Permethrin 5% cream	Topically 8–12 h; repeat in 7–10 days	Currently treatment of choice
Lindane shampoo 1%	Topically 5 min	Risk of central nervous system toxicity
Occlusive agent (Vaseline)	Applied to eyelashes twice daily for 8 days; manual removal of nits	None
Ivermectin, oral	250 μg/kg dose given 7 to 10 days apart demonstrated effective for eyelash involvement	Risk profile, see Box 208-4

neously, but other family members need not be treated if there is no evidence of infestation (Box 208-7).[60,61]

TREATMENT FAILURE Treatment failure is usually a result of failure to follow instructions, neglecting to treat sexual contacts, or re-infestation. Patients with human immunodeficiency virus/acquired immunodeficiency syndrome tend to have more severe infestations with pediculosis pubis and to be unresponsive to conventional therapy.[62] Persistent itching may be caused by irritation from the pediculicide (usually because of overuse) or patient anxiety. Parasitophobia is fairly common after infestation and is difficult to treat.

CHAPTER 209

Bites and Stings of Terrestrial and Aquatic Life

Jennifer S. Daly
Mark Jordan Scharf

The Book of Genesis promised humans dominion over the fish of the sea and every living thing that moved on the face of the earth. Unfortunately, it did not guarantee that every encounter between human and beast would be free from harm. The first section of this chapter considers the harmful effects of the bites of land animals, including snakes, as well as the bacterial and viral infections they may transmit. The second section reviews bites and stings and other forms of injury that may be inflicted by marine life.

BITES OF LAND ANIMALS

Epidemiology

Dog bites account for 80 percent to 90 percent of all mammalian bites involving humans. Four million to 5 million dog bites are estimated to occur each year in the United States, and, in 2001, it was estimated that 368,245 persons were treated for dog bite–related injuries.[1] The human victim is often a 5- to 9-year-old boy who may have been teasing or playing with the dog. Sometimes the bite occurs when a person is trying to break up a pair of fighting dogs or trying to aid an animal. In the United States 4 percent to 5 percent of dog bites are work related and include bites sustained by postal carriers. Overseas a higher percentage are produced by untamed animals.[2–4] Most dog bite injuries involve the upper extremities, especially the hands. Cat bites are the second most common type of mammalian bite after dog bites, but the wounds are nearly twice as likely to become infected as wounds from dog bites.[5]

Clinical Approach (Pathogenesis and Treatment)

The evaluation and treatment of all bite wounds should include taking a careful history of the incident, the type of animal, the site of the bite, and the geographic setting. Hand wounds, puncture wounds, and crush injuries are likely to become infected. Specimens from infected bites should be cultured and a Gram-stained smear prepared; the wound should then be washed,

BITES AND STINGS AT A GLANCE

- Dog bites account for 80 percent to 90 percent of all mammalian bites involving humans, but cat bites are more likely to become infected.
- Whether or not post-exposure prophylaxis with rabies immune globulin and human diploid cell rabies vaccine is needed depends on the circumstances surrounding the bite.
- In the United States, there are approximately five to six deaths from snakebites and probably 6000 to 7000 snakebite envenomations each year.
- Most stingray injuries occur when bathers, waders, or fishermen accidentally step on rays as they lie partially covered with sand in shallow waters. The extreme pain caused by the venom may be relieved by soaking the affected body part in very warm water.

well irrigated, and left open. Most patients with bites on the hands, deep cat bites, deep cat scratches, and sutured wounds should be treated with amoxicillin/clavulanic acid or ceftriaxone because of the risk of *Pasteurella multocida* infection; if the patient is allergic to these agents a quinolone or a tetracycline should be used. Evidence that the use of prophylactic antibiotics is of benefit exists only for bites of the hand. However, once the patient has an infection, intravenous antibiotics and surgical drainage are often required.[4,6–8] Tetanus immune status should be evaluated, and rabies prophylaxis should be considered, depending on the type of animal, local epidemiologic factors, and ability to quarantine the animal for 10 days.[9]

Human bites and monkey bites deserve special mention, because 30 percent become infected with aerobic or anaerobic mouth organisms. Infection caused by anaerobes may spread through the metacarpal–phalangeal space and cause severe damage. The same procedure should be followed as for other animal bites; that is, culture and Gram stain, thorough washing, and débridement. Wounds, especially hand wounds, should be left open if possible. Evidence suggests that patients with human bites that penetrate the epidermis should be treated prophylactically with amoxicillin/clavulanic acid for 7 to 10 days or, if the patient is allergic to penicillins, with a fluoroquinolone plus an antianaerobic agent such as clindamycin.[7,10] Clenched-fist injuries should be evaluated by a hand surgeon because of the high likelihood of infectious complications, including septic arthritis and osteomyelitis.[2]

Specific Bacterial Infections Caused by Animal Bites

***PASTEURELLA MULTOCIDA* INFECTION** (See Chap. 183) An organism commonly infecting bite wounds is *P. multocida,* a bacterium present in the nasopharynx in 50 percent to 66 percent of dogs and 70 percent to 90 percent of cats. The most common pattern is that of local infection with adenitis after a dog or cat bite or scratch. *P. multocida* is the most common pathogen in cat-bite infections and may also complicate 26 percent of dog-bite wounds.[5] The infection usually presents within 24 to 48 hours, often within several hours. In patients with a cat bite, the infection may be followed by tenosynovitis or osteomyelitis as a result of inoculation of the organism into the periosteum by the long, sharp tooth of the animal. *Pasteurella* infections have also been reported after bites of large cats such as lions and tigers.

Treatment of the patient with presumptive *P. multocida* infection should consist of careful washing of the wound and an attempt to leave it open. The empiric antibiotic of choice is amoxicillin/clavulanic acid orally for 7 to 10 days, with careful follow-up examination of the wound. *P. multocida* is susceptible to penicillin alone, and patients may be switched to penicillin if they have a pure infection with this organism. A fluoroquinolone, a tetracycline, and trimethoprim-sulfamethoxazole are alternatives. In most patients the antibiotic is aimed at both the patient's skin flora (such as *Staphylococcus aureus*) and organisms from the animal's mouth.

***STAPHYLOCOCCUS INTERMEDIUS* INFECTION** *S. intermedius* is an organism associated with dogs weighing more than 40 pounds. It is more commonly found in canine gingival flora than is *S. aureus* (39 percent versus 10 percent).[11] It is a Gram-positive, coagulase-positive coccus that can be differentiated from *S. aureus* in the laboratory by biochemical testing. In comparison with *S. aureus*, *S. intermedius* does not produce acetoin from glucose and has β-galactosidase activity. If these tests are not performed (i.e., if only a latex assay is use to identify staphylococci), the laboratory may incorrectly report an isolate as *S. aureus* or unspecified staphylococcus. Antibiotic treatment is the same as that for infections with *S. aureus*, although resistance to oxacillin is uncommon in *S. intermedius* and is growing in importance for *S. aureus*.

***CAPNOCYTOPHAGA CANIMORSUS* INFECTION** *Capnocytophaga canimorsus* is a capnophilic ("carbon dioxide–loving"), facultatively anaerobic, slow-growing, Gram-negative rod associated with dog bites.[12–15] The organism has been found in the oral cavity of 17 percent of cats and 24 percent of dogs. Most infections occur in splenectomized or immunocompromised hosts, although fatal infections including meningitis have been reported in immunocompetent hosts and present as overwhelming sepsis.

INFECTION BY *PORPHYROMONAS* SPECIES *Porphyromonas* sp. are slow-growing anaerobic bacteria found in the deep gingival pockets of animal and humans that are difficult to culture, requiring 4 to 6 days for colony formation as well as vitamin K and hemin in the media.[16,17] Citron and co-workers[18] found *Porphyromonas* species in 28 percent of culture specimens from patients with infected dog- and cat-bite wounds.

CAT-SCRATCH DISEASE *Bartonella henselae* is the most common etiologic agent of cat-scratch disease. *Afipia felis* and other *Bartonella* species may cause some cases (see Chap. 182).

PLAGUE (See Chap. 183)

TULAREMIA (See Chap. 183)

RAT-BITE FEVER (See Chap. 183)

Specific Viral Infections Caused by Animal Bites

RABIES ***Epidemiology.*** The most notorious viral disease to occur after an animal bite is rabies, which is caused by an RNA virus. Its epidemiology has changed in the past few years as a result of improved control of rabies in the domestic animal population. Now, nonimmune dogs and domestic animals account for only 8 percent of cases, whereas sylvatic animals, such as skunks, raccoons, red and gray foxes, and bats, represent the greatest potential danger. Rodents, such as squirrels and hamsters, are probably inconsequential as sources of rabies. However, cases of rabies in cattle are increasing.[19] Post-exposure prophylaxis, which is nearly 100 percent effective, has reduced the number of cases of human rabies from more than 100 per year a century ago to an average of 1 to 4 cases a year in the United States today. In 2004, of the eight cases in the 49 states and Puerto Rico, four were acquired as a result of patients' receiving transplanted organs from an infected donor.[19,20]

Live virus is introduced into nerve tissue at the time of the bite, multiplies at the site, and then spreads to the central nervous system. It replicates in gray matter and then spreads along autonomic nerves to the salivary glands, adrenal glands, and heart. The incubation period varies with the site of the bite from 5 days to as long as several years. Clinical features include a prodromal period of 1 to 4 days, followed by high fever, headache, and malaise. Paresthesia at the site of inoculation occurs in 80 percent of patients. The next sequence of events is familiar: agitation, hyperesthesia, dysphagia, excessive thirst, paralysis, and death.

Diagnosis. The diagnosis of clinical rabies is difficult and is often not made until after the death of the patient. Viral

isolation methods may yield positive results for specimens of saliva or cerebral spinal fluid during the first 2 weeks of the illness, and saliva is infectious, so isolation precautions are needed. Serum antibodies may be detected as early as day 6 and usually by day 13. The fluorescent antibody method for detection of the viral antigen is the most rapid and sensitive means of making the diagnosis, and no matter where the actual bite site, once patients have central nervous system disease, the diagnosis can be made from a biopsy of skin from the highly innervated hair-covered area of the neck or from brain tissue.

Prevention and Treatment. The most effective prevention for rabies is to avoid contact with any wild animal or any unfamiliar domestic animal. Persons at risk of unavoidable contact with rabies, such as spelunkers, veterinarians, virologists, and travelers spending time in countries where rabies is enzootic, should receive pre-exposure prophylaxis with the human diploid cell rabies vaccine (HDRV) series (three intramuscular injections on days 0, 7, and 21 or 28) given in the deltoid muscle and repeated every 2 years. In persons vaccinated intradermally (using a lower intradermal dose), the neutralizing antibody titer should be followed, because the immune response may not be fully protective.[21]

The need for post-exposure prophylaxis can be determined by the answers to the following questions: What is the status of animal rabies in the locale where the exposure took place? Was the attack provoked or unprovoked? Of what species and size was the animal? What was the state of health and vaccination record of the animal? Will the brain of the animal be examined within 48 hours? Can the animal be effectively quarantined? Most animals transmit rabies virus in saliva only a few days before becoming ill themselves; bats, however, may harbor the virus for many months.

Bites by Household Pets. If the dog or cat responsible for the bite is healthy and available for observation for 10 days, the patient should not be treated unless the animal develops rabies. At the first sign of rabies in the animal, the patient should be treated with rabies immune globulin (RIG) and the vaccine HDRV. The symptomatic animal should be killed and tested as soon as possible. If the animal is rabid or suspected of being rabid, or if it does not have up-to-date vaccination records, the patient should be treated with RIG and HDRV (see Specifics of Treatment later).[22]

Bites by Wild Animals. All skunks, bats, groundhogs, foxes, coyotes, raccoons, bobcats, and other carnivores should be regarded as rabid unless laboratory test results prove negative. The patient should be treated with RIG and HDRV.

Bites by Other Animals. Bites by other animals (livestock, rodents, lagomorphs such as rabbits and hares, and ferrets) should be considered individually.[22] Local and state public health officials should be consulted about the need for prophylaxis. Bites by squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice, and other small rodents almost never call for anti-rabies prophylaxis.

Specifics of Treatment. The most important step is to cleanse the wound immediately with a brush and soap to remove as much virus as possible. The wound should be rinsed well and then scrubbed a second time with green soap or 70 percent alcohol, which is rabicidal. If vaccine treatment is indicated, both RIG and HDRV should be given as soon as possible, regardless of the interval after exposure, unless the patient has been previously vaccinated and a serologic assay shows current immunity. In this case, only HDRV is needed and should be given on day 0 and day 3.[9] For nonimmune hosts, administration of RIG is the most urgent. If HDRV is not immediately available, RIG should be started and HDRV given as soon as it is obtained. RIG (20 IU/kg) should be given immediately—50 percent around the site of the bite and 50 percent in the thigh or the arm. This passive immunization will result in the early appearance of antibody but will also inhibit development of the active antibody from HDRV, hence the need for a 28-day series. Active immunization is accomplished using HDRV, given intramuscularly for a total of five doses on days 0, 3, 7, 14, and 28. Serum for rabies antibody testing should be collected 2 weeks after the fifth dose. If there is no antibody response, an additional booster should be given.

Management of the Patient with Clinical Rabies. In the rare cases in which a patient is admitted with the clinical diagnosis of rabies, several steps should be taken immediately. First, the diagnosis must be suspected and the patient placed in isolation precautions while the diagnosis is made rapidly by fluorescent antibody staining of specimens from various tissues, as well as immunofluorescence staining of the source animal's brain tissue. Elevated antibody titers in the absence of immunization are clear evidence of infection. The first signs of clinical rabies are usually non-specific, such as malaise, anorexia, fatigue, headache, and fever. The acute neurologic illness that follows is most commonly characterized by intermittent episodes of hyperactivity. In some cases, however, a progressive paralysis is most common. The usual period from onset of symptoms to onset of coma is 10 days. Risk of exposure for hospital staff includes contact with open wounds or mucous membranes with saliva or other potentially infectious material such as neurologic tissue, spinal fluid, or urine. Blood, serum, and stool are not considered infectious.

Basic clinical management consists of anticipating and preventing all treatable complications of the rabies infection and induction of coma to manage the patient until the patient generates an immune response.[23] Pulmonary hypoxia should be prevented by tracheostomy at the first sign of respiratory difficulty, monitoring of actual partial pressure of oxygen, and use of supplemental oxygen. There are no specific antiviral treatments for rabies, although ribavirin has been tried.[23] Anticonvulsant therapy should also be instituted. Extreme increases in intracranial pressure may be prevented by insertion of a cerebrospinal fluid reservoir that allows withdrawal of the intraventricular fluid and measurement of intracranial pressure. Cardiac arrhythmias may be anticipated with careful monitoring. Rabies had been regarded as uniformly fatal, but there have been patients who have survived with prolonged cardiorespiratory support, and there is serologic evidence that some animals have survived. An aggressive approach to treatment of the patient with known rabies infection is worthwhile. In 2004, a 15-year-old girl without a history of prior rabies vaccination survived after her physicians used a treatment based on induced coma as well as other supportive measures and antiviral agents.[19,23]

LYMPHOCYTIC CHORIOMENINGITIS

HERPESVIRUS SIMIAE (B VIRUS) INFECTION Herpesvirus simiae (B virus) is enzootic in Old World monkeys, espe-

cially rhesus, cynomolgus, and other macaques. The illness in monkeys is similar to that caused by herpes simplex in humans, and asymptomatic monkeys may shed the virus in saliva. Most cases in humans have occurred after direct exposure to macaque monkeys or monkey tissue through bites, scratches, or cuts.[27] A vesicular lesion develops at the wound site with progressive lymphadenitis and fever. Over the next few days to weeks patients develop a severe illness, which is characterized by rapidly progressive ascending neuropathy and encephalitis. The illness is rare and in 72 percent of cases has been fatal. A cluster of four cases occurring in 1987 in Pensacola, Florida, were treated with acyclovir. The two patients who received acyclovir when their infections were localized responded well to therapy and were maintained on oral acyclovir. All macaques should be presumed to be shedding B virus and should be handled accordingly. All monkey-inflicted injuries should be cleansed, specimens should be collected for viral culture, and a physician should evaluate the patient. Clinical and serologic monitoring is critical, and high-risk or infected patients should be treated according to established guidelines. The use of acyclovir or ganciclovir initially and acyclovir for years has led to improved survival in infected patients.

Snakebites

In the United States, there are approximately five to six deaths from snakebites and probably 6000 to 7000 snakebite envenomations each year.[28] The largest number of venomous snakebites occur in the southwestern states. Worldwide as many as 30,000 fatal snakebites may occur each year. Because of regional differences in varieties of snakes, management recommendations differ by geographic area.

The two major poisonous snakes in the Americas are the pit viper (family Viperidae, subfamily Crotalinae, which includes the rattlesnake, water moccasin, and copperhead) and the coral snake (family Elapidae). Poisonous snakes are found in all states of the United States except Maine, Hawaii, and Alaska.[28] The northern copperhead, also called the *highland moccasin*, is pink or reddish brown and is marked with large chestnut-brown barrels resembling dumbbells or hourglasses (Fig. 209-1). The bite is painful but rarely fatal. The timber rattler is dark brown with chevrons of black and brown (Fig. 209-2).

▲ **FIGURE 209-1** Northern copperhead.

The degree of toxicity of a snakebite depends on the potency of the venom, the amount injected, the size and condition of the snake, and the size of the person bitten. Pain occurs at the site of the bite (usually within 5 minutes). Signs and symptoms at the bite site include wheal with local edema, numbness, and, within moments, ecchymosis and painful lymphadenopathy (Fig. 209-3).

Nausea, vomiting, sweating, fever, drowsiness, and slurred speech may develop. Bleeding of the gums and hematemesis are common hemorrhagic manifestations. If edema and erythema have not developed within 8 hours after the bite, it can be assumed that significant envenomation did not occur. Estimated mortality rates for victims who receive antivenom in a health care facility are less than 1 percent and probably less than 0.1 percent.

For proper treatment, it is extremely important to establish that the bite is from a poisonous snake. Many patients experience symptoms related to fear that may mimic symptoms from venom. The patient should have distinct fang punctures and immediate local pain, followed by edema and discoloration within 30 minutes. It is helpful to inspect the snake, because those that are poisonous may be differentiated from those that are not by the presence of fangs and the shape of the pupils (Fig. 209-4). Availability of a photograph of snakes common to a specific geographic area is important for all hospital emergency wards to aid practitioners in deciding if the patient has been bitten by a poisonous snake.

Although there are still insufficient evidence-based criteria for first aid and out-of-hospital treatment for snakebite envenomations, a rational approach is outlined in Table 209-1.[29] In summary, the patient should be stabilized and transported as rapidly as possible to a health care facility capable of administering antivenom, and the affected site should be immobilized below the level of the heart. Constricting bands such as watches or jewelry should be removed; the use of venous compression bands is not recommended.[28] The patient should be kept as immobilized as possible.[28] Venous compression techniques are de-

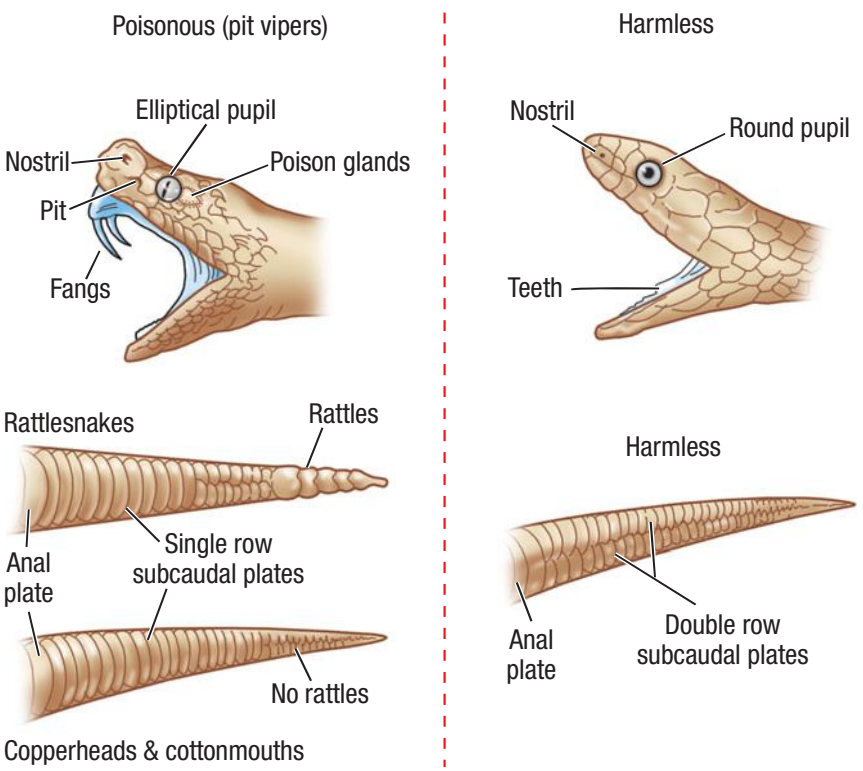
▲ **FIGURE 209-2** Timber rattlesnake.

▲ **FIGURE 209-3** Copperhead snakebite.

signed to impede the return of venous and lymphatic flow from the bite site without sacrificing blood flow to the extremity. In cases in which there is likely to be a significant delay in transport and the victim is developing systemic signs of envenomation such as hypotension, these techniques may be of value.[29] Arguments against the use of venous compression techniques include the time that it takes to apply the treatments, which may further delay transport time. Additional arguments against the use of these techniques include the potential for concentrating the venom in the affected limb, which may worsen local necrosis, along with the possibility of a bolus effect when the compression is released.[29] Another possible disadvantage of the use of these compression techniques is the potential for them to cause arterial compression if the affected limb swells in reaction to the toxin. If a decision is made to use a venous compression band in the field, arterial pulses should be palpable distal to the ligature, and the dressing should be checked frequently to make sure that it is has not become too tight. If a venous compression dressing has been applied in the field and is not causing vascular compromise, it should be left in place until the patient reaches a health care facility and antivenom is at the bedside.[29]

TABLE 209-1
First Aid and Out-of-Hospital Treatment for Snakebite Envenomation

1. The patient should be stabilized and transported as rapidly as possible to a health care facility capable of administering antivenom.
2. The affected site should be immobilized below the level of the heart, constricting bands such as watches or jewelry should be removed, and the patient should be kept as immobile as possible.[28]
3. The use of venous compression bands or pressure immobilization is not recommended,[28] although there is controversy surrounding their use if there is likely to be a significant delay in transport and the victim is developing systemic signs of envenomation such as hypotension, and in such a case these techniques may be of value.[29]
4. The value of using a suction device to extract venom is debated in the literature.[28] If such a device is applied in the field and fluid is accumulating in the suction cup, it can be left in place until the patient reaches a medical facility.[29]
6. The use of cryotherapy, incision, or excision of the bite site, arterial tourniquets, and electroshock therapy as part of emergency field therapy should be discouraged.



▲ **FIGURE 209-4** Identification of poisonous and nonpoisonous snakes. (From Wingert WA, Wainschel W: A quick handbook on snake bites. *Resid Staff Physician*, 1977, p 56, with permission.)

The role of surgical intervention in the treatment of snakebite envenomations is limited in most cases. Surgery is appropriate only if medical treatment, including elevation of the bitten body part in conjunction with the administration of four to six vials of Crotalidae polyvalent immune Fab (ovine) (FabAV) over the course of 1 hour, fails.[28] Débridement of truly necrotic skin and subcutaneous tissues is recommended 4 to 5 days after envenomation. In cases of bites to a digit, if there is severe swelling and the finger is tense, blue, or pale, a digit dermotomy may be of use. True compartment syndrome involving an extremity is a rare complication of snakebite envenomation. Fasciotomy should be used only in cases of increased compartment pressure that has not responded to prompt and sufficient treatment with antivenom.[30]

The primary treatment for crotaline snake venom poisoning is prompt and adequate dosing with antivenom. Antivenom is most effective if given within 4 hours of the snakebite (Box 209-1).

FabAV should be used for all severe American crotaline snakebites except

Box 209-1

Antivenom for Crotaline Snake Bites

- Emergency information and antivenom are available in the United States through the nationwide poison control center network, which can be reached 24 hours a day by calling 800-222-1222.[28]

those of the coral snake. The dosage should be guided by the severity and progression of local changes and systemic clinical signs. Because some patients develop recurrent manifestations of envenomation after initial treatment, both a loading dose of four to six vials of FabAV and then, once initial control has been achieved, three maintenance doses 6, 12, and 18 hours later are recommended.[28]

Supportive treatment is indicated, including hospitalization with careful evaluation of baseline hematocrit, platelet count, and prothrombin time. Coagulopathy should be corrected by using antivenin, because fresh frozen plasma is ineffective.[28] The wound should be cleansed and covered. Antitetanus therapy and antibiotic prophylaxis with penicillin, ampicillin/sulbactam, or tetracycline should be initiated for severe bites.

BITES AND STINGS OF AQUATIC ORGANISMS

Seal Bite

Normally, a seal bite occurs on the finger of a trainer or a seal hunter—thus the term *seal finger* or *spaek finger*.[31,32] The etiologic agent is unclear and is controversial. One study suggests that a virus similar to that causing orf may be the culprit,[32] although *Mycoplasma* sp. have been isolated, and some patients respond to tetracycline (see Chap. 183). The incubation period of 4 to 8 days is followed by throbbing pain, erythema at the site, and swelling of the joint proximal to the bite. Untreated, seal finger progresses to cellulitis, tenosynovitis, and arthritis. Tetracycline, 500 mg orally four times a day for 10 days, remains the antibiotic of choice.[29,31] It is also helpful to immobilize and elevate the finger as well as soak it several times a day.

Injuries Caused by Jellyfish, Portuguese Man-of-War, Sea Anemones, and Corals

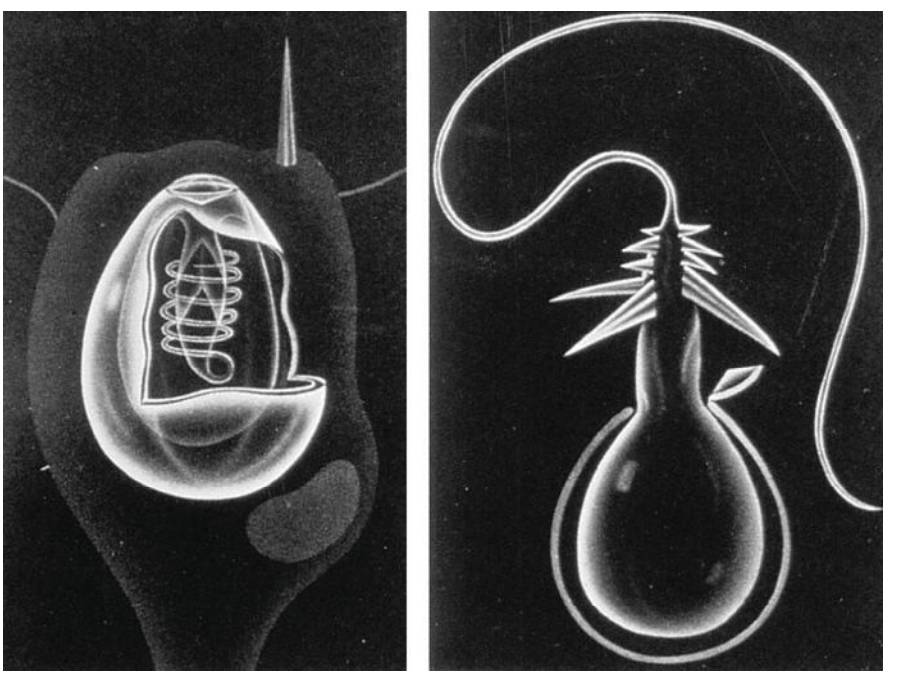
Stings caused by jellyfish, Portuguese man-of-war, sea anemones, and corals are the most common envenomations experienced by humans in marine environments. All of these creatures are members of the phylum Cnidaria, formerly known as *Coelenterata*. They are divided into three major classes. The first class, Hydrozoa, includes the Portuguese man-of-war, fire corals, and hydroids. Jellyfish belong to the second class, Scyphozoa. The third class, Anthozoa, encompasses sea anemones and true corals. Approximately 100 of the 9000 species of Cnidaria that have been identified may cause injury to humans.[33]

Cnidarians are radially symmetric animals with body walls formed by an inner and outer layer of cells enclosing a jelly-like substance. They may be either free floating in the water like jellyfish or sessile like corals.[33] Almost all cnidarians possess nematocysts, or stinging capsules, which are usually concentrated on some form of tentacle. Each nematocyst contains a toxin or group of toxins and a coiled thread-like apparatus with a barbed end that functions like a flexible hypodermic syringe (Fig. 209-5). When the nematocyst comes into contact with a victim, the barbed end is discharged, and the toxin is injected into the skin.

Cnidarian stings range from mild, self-limited irritations to extremely painful and serious injuries, depending on the toxin of the species involved and the magnitude of the envenomation. Stings from certain species such as the cubomedusae, or box jellyfish, can be fatal.

In most cases, jellyfish stings elicit toxic reactions that may be localized and/or systemic. Although immediate-type hypersensitivity reactions, including urticaria, angioedema, and anaphylaxis, occur less frequently, they require prompt medical intervention, because shock and death may ensue in highly sensitized individuals. Allergic contact dermatitis, delayed and persistent hypersensitivity reactions, granuloma annulare,[34] and erythema nodosum are other possible cutaneous reactions to jellyfish stings.

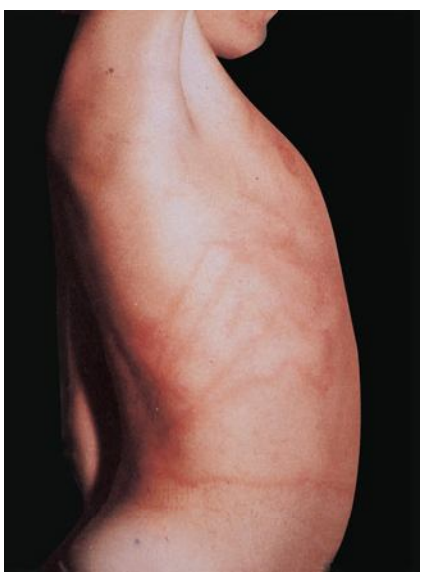
INJURIES CAUSED BY JELLYFISH ***Sea Nettles.*** Among the organisms most commonly causing jellyfish stings are the sea nettles, which comprise two different species, both of which inhabit Atlantic as well as Indo-Pacific waters. *Cyanea capillata* and its relatives is the larger of the two species, with a bell measuring up to 1 m and numerous tentacles reaching 30 m in length[35] (Fig. 209-6). *Chrysaora quinquecirrha* is smaller, with a white or rusty bell that may reach 30 cm with four digestive tentacles hanging from it. Although sea nettle stings are seldom lethal, they can be quite painful.[36] Initially the victim experiences a sharp burning pain in the area contacted by the tentacles. Within minutes, the sting area develops a zigzag, whip-like pattern of raised red welts 2 to 3 mm wide (Fig. 209-7). The duration of acute pain may vary, but the pain often begins to abate in 30 minutes. The wheals usually subside by 1 hour, but purplish brown petechial and post-inflammatory pigmentation may persist for several days.



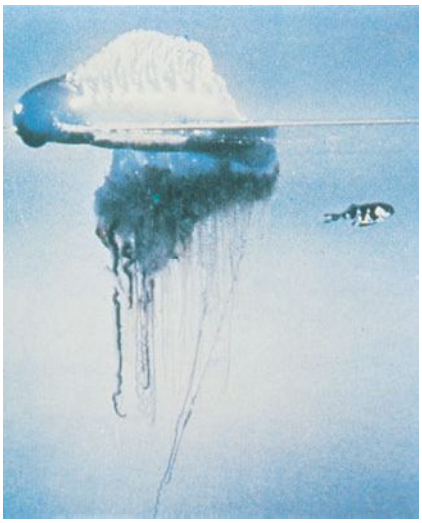
▲ **FIGURE 209-5** From left to right, a diagrammatic view of an intact and discharged coelenterate nematocyst. (R. Kreuzinger, used with permission from World Life Research Institute.)

▲ **FIGURE 209-6** *Cyanea capillata,* also known as *sea nettle* or *lion's mane*, is a common cause of jellyfish stings. (B. W. Halstead, used with permission from World Life Research Institute.)

Portuguese Man-of-War. *Physalia physalis* is the species name for the Portuguese man-of-war, which is a member of the class Hydrozoa and is therefore not a true jellyfish. *P. physalis* is encountered in both Atlantic and Mediterranean waters, and is easily recognized by its translucent blue to pink or purple bladder-like float with multiple tentacles (Fig. 209-8). *P. physalis* is distinguished from its Pacific ocean relative *P. utriculus*, commonly known as the *blue bottle*, by its larger bell, which ranges in size from 10 to 30 cm, and multiple fishing tentacles extending up to 30 m; in contrast, *P. utriculus* has only a single tentacle that rarely exceeds 5 m.[37] These tentacles are



▲ **FIGURE 209-7** Whip-like sting pattern caused by *Cyanea capillata* in a young boy. (J. H. Barnes, used with permission from World Life Research Institute.)



▲ **FIGURE 209-8** *Physalia physalis*, the Portuguese man-of-war, is distinguished by its bladder-like float and numerous trailing tentacles. (B. W. Halstead, used with permission from World Life Research Institute.)

armed along their entire length with hundreds of thousands of nematocysts arranged in stinging batteries, with each battery containing hundreds of nematocysts. The nematocysts remain active even after portions of the tentacles are broken off in storms or when these animals are stranded on the shoreline by high winds or waves. A beached Portuguese man-of-war can cause a severe sting when stepped on or touched. Children who are stung after handling these animals and then cry and rub their eyes may develop an acute conjunctivitis.

Stings of *P. physalis* are more painful and severe than those caused by sea nettles and are more extensive and serious than those caused by *P. utriculus*. At the moment of contact with the tentacles of *P. physalis*, the victim experiences a sharp, shock-like, burning pain. There may be painful paresthesias or numbness in the sting area. Initially, the sting area appears as an irregular single line or multiple lines composed of red papules, beaded streaks, or erythematous welts that correspond to the areas of tentacle contact. The wheals resolve in hours but may progress to vesicular, hemorrhagic, necrotic, or ulcerative stages before healing[38] (Fig. 209-9).

Post-inflammatory striae may persist for weeks to months. Severe localized complications of *P. physalis* stings may also include arterial spasm in the sting site that can result in distal digital gangrene.[39,40]

Within 10 to 15 minutes of a *Physalia* sting, the victim may develop symptoms of an envenomation reaction characterized by nausea, abdominal cramps,

▲ **FIGURE 209-9** This diver surfaced directly under a large Portuguese man-of-war and suffered a severe sting with bulla formation and tissue necrosis. (S. Anderson, used with permission from World Life Research Institute.)

muscular pains, backache, irritability, dyspnea, and chest tightness. Intravascular hemolysis and acute renal failure were reported in a 4-year-old girl after a severe sting by *P. physalis*.[41] Most reports of death due to stings of *P. physalis* are not well documented, but well-substantiated case reports of human fatalities do exist.[42–44]

Cubomedusae [Class Cubozoa]: Box Jellyfish. Of all the species of jellyfish that cause painful stings and distress to swimmers, the species with the most established record of lethality are the cubozoans. *Chironex fleckeri* or box jellyfish causes at least one death each year in Australia.[45] The fatality is usually a child, presumably because the size of the victim and the total area of the sting determine the likelihood of death. Until recently, most of the published cases of *C. fleckeri* stings involved fatal or nearly fatal envenomations, but less serious stings do occur in endemic areas.[46–48]

C. fleckeri (commonly known as the *sea wasp*) is an advanced species of jellyfish, with a semitransparent cubic bell that may grow to a volume of 9 L and weigh more than 6 kg[45] (Fig. 209-10). Trailing from the bell are up to 60 stinging tentacles, which may reach 2 to 3 m in length. When a human comes into contact with a box jellyfish, some of the tentacles are torn off and adhere to the skin. Rescuers of *C. fleckeri* sting victims must exercise caution, because they also are at risk of envenomation until the tentacles have been neutralized and removed.

The stings appear initially as linear welts that give the patient the appearance of having been whipped.[45] Fresh stings of *C. fleckeri* are easily recognized

▲ **FIGURE 209-10** The deadly box jellyfish, *Chironex fleckeri*, is found in Indo-Pacific waters off the coast of Northern Australia. (Used with permission from R. Hartwick.)

because they have a diagnostic, frosted, cross-hatched or ladder-like appearance (Fig. 209-11). Microscopic diagnosis is also possible from blade scrapings or tape strippings from the sting site. The intense pain may persist for many hours. Severely stung areas of skin take on a dusky cyanotic appearance and blister formation and necrosis may occur. The healing process is slow and may be complicated by bacterial superinfection and scarring.

▲ **FIGURE 209-11** Characteristic frosted cross-hatched tentacle marks diagnostic of a sting caused by *Chironex fleckeri*. (Used with permission from Townsville General Hospital, Department of Medical Illustration, Townsville, Queensland, Australia.)

Death may ensue within minutes due to cardiotoxic and neurotoxic agents in the venom that can produce ventricular arrhythmias and cardiac arrest, and respiratory failure, respectively.[47] Intravascular hemolysis caused by the toxin can precipitate acute renal failure. First aid for these victims frequently involves cardiopulmonary resuscitation. Intravenous verapamil has been proposed for both treatment and prophylaxis of ventricular arrhythmias.[49,50] Antivenin is available for *C. fleckeri* stings, and its early use in severe envenomations may be lifesaving and significantly reduces the pain and inflammation at the sting site.[46]

Irukandji syndrome is a severe and delayed response (usually 30 minutes but between 5 and 40 minutes) to the sting of a small box jellyfish, termed the *Irukandji jellyfish*, that has resulted in the death of two tourists in the Cairns–Port Douglas region of Australia.[51] The classic syndrome consists of local signs of inflammation together with severe back pain, excruciating muscle cramps, piloerection, sweating, nausea, vomiting, headache, and palpitations. The most severe cases may progress to include extreme hypertension and cardiac failure. Only one species, *Carukia barnesi*, has been clearly linked to this syndrome, but it is thought that at least six different species of small jellyfish, each with only one tentacle arising from each corner of the bell (carybdeids), may be etiologic agents. The stings most often occur in deep water. Treatment includes application of vinegar to discharge nematocysts and victim transport for medical attention including pain control and α blockade, because the venom is thought to act as a presynaptic neuronal sodium agonist and to stimulate norepinephrine release.

Prevention and Treatment of Jellyfish Stings. Tables 209-2, 209-3, and 209-4 give details on the prevention of jellyfish stings and first aid for and treatment of the stings. Systemic reactions may occur, and the treatment for these includes support of vital functions with cardiopulmonary resuscitation, oxygen, and intravenous fluids.[52,53] Application of a venous-lymphatic constriction bandage proximal to the wound site should be considered in the case of severe stings when systemic reactions are present or likely to occur, when topical deactivation of tentacles is not possible, and when transport to receive specific antivenin for *C. fleckeri* stings is available. The antivenin is prepared from sheep serum and may therefore pose a risk of allergic reaction in sensitive individuals.[34,36] The preferred route of administration is intravenous, but the antivenin may be given intramuscularly. In severe stingings, it has proved lifesaving. It is also the only treatment that can alleviate the intense pain and may reduce inflammation at the

TABLE 209-2
Prevention of Jellyfish Stings

1. Swim only at patrolled beaches with properly trained lifeguards and adequate treatment facilities.
2. Avoid swimming in infested waters, especially after a storm, because stings may result from remnants of floating damaged tentacles.
3. Beware of apparently dead or beached jellyfish.
4. When snorkeling or scuba diving, wear protective clothing such as a wet suit, long-sleeved shirt, pants or long woolen underwear, and gloves. In areas where Irukandji syndrome occurs, wear a Lycra stinger suit.
5. Use sunblock containing jellyfish and "sea lice" repellent.
6. Bathing beaches should be closed during periods of high jellyfish infestation.

Data from McKinney PE: Out-of-hospital and interhospital management of crotaline snakebite. *Ann Emerg Med* **37**:168, 2001; Kimball AB et al: Efficacy of a jellyfish sting inhibitor in preventing jellyfish stings in normal volunteers. *Wilderness Environ Med* **15**:102, 2004; and Harrison SL et al: Reported knowledge, perceptions, and behavior of tourists and North Queensland residents at risk of contact with jellyfish that cause the "Irukandji syndrome." *Wilderness Environ Med* **15**:4, 2004.

TABLE 209-3
First Aid Treatment of Jellyfish Stings

1. Remove or rescue the victim from the water.
2. Stabilize vital functions: Airway, breathing, circulation.
3. Immobilize the affected part to prevent further envenomation by adherent tentacles.
4. Identify the type of jellyfish sting by considering locale, time of year, and indigenous species and by observing the sting pattern. Preserve a portion of the tentacle for future identification. Tape-strip or scrape the sting site for microscopic analysis of the nematocysts if no tentacles are available.
5. To prevent further envenomation of the victim and to reduce the chance of a sting to the rescuer, disarm the nematocysts before removing the adherent tentacles.

Data from refs. 46, 47, 52, 53, 105, and 106.

TABLE 209-4
Organism-Specific and Follow-Up Treatment of Jellyfish Stings

1. If *Chironex fleckeri* or other box jellyfish species that cause the Irukandji syndrome are suspected, douse or spray dilute acetic acid (3%–10%) or household vinegar over all areas of tentacle contact for at least 30 s.[46,47,51,105,106]
2. For sea nettles, mix sodium bicarbonate (baking soda) with water to form a slurry and pour over the affected area or apply the powder directly to the tentacles.[107]
3. For *Physalia physalis* stings, a slurry of baking soda is indicated. Vinegar had been reported to neutralize nematocysts of *P. physalis*, but work with species from Australia indicate that it may cause a discharge of nematocysts in some cases.
4. If vinegar or baking soda is unavailable, papain, available as a powdered meat tenderizer, may be applied directly as a powder or mixed in water as a slurry to sting areas and tentacles of both sea nettles and Portuguese man-of-war.
5. If nothing else is available, the tentacles can be rinsed off with seawater.
6. Do not use fresh water, methylated spirits, or alcohol in any form to deactivate tentacles, because these all may cause a rapid massive discharge of nematocysts.
7. After the tentacles have been disarmed, they may be carefully removed with a forceps or gently scraped away from the skin with shaving cream and a razor or a plastic card, shell, or knife.[59,70,91]

sting site and decrease the chance of scarring. Intravenous administration of verapamil has been advocated for both treatment and prophylaxis of arrhythmias.[49,50] For pain in severe stingings, parenteral narcotic analgesics and ice packs, as well as antivenin, should be considered. Local reactions may be treated with topical anesthetic ointments, creams, lotions, or sprays to relieve itching or burning pain.[33] For delayed-type hypersensitivity reactions, topical glucocorticoids, antihistamines, and systemic glucocorticoids should be used if necessary.[35]

Secondary infections should be treated with the appropriate parenteral antibiotics, and antitetanus therapy should be considered. Application of ice or cold packs can relieve the pain of mild to moderate stings of many types of jellyfish, and aspirin or acetaminophen, alone or in combination with codeine, can be used to relieve persistent pain.

SEA ANEMONE DERMATITIS Sea anemones are members of the phylum Cnidaria, class Anthozoa. They are sessile creatures with flowery tentacles armed with nematocysts (Fig. 209-12). The stings of sea anemones may cause dermatitis in sponge fishermen, sponge divers, and beachcombers who gather snails and crabs from rocky hollows along the shore. Their toxicity to humans depends on the species. After the immediate reaction has subsided, delayed-type hypersensitivity reactions can develop at the site of a sting from a sea anemone (Fig. 209-13).

▲ **FIGURE 209-12** The flowery tentacles of the sea anemone can cause envenomations similar to jellyfish stings. (Used with permission from Marty Gilman, Worcester, MA.)

The genus *Sagartia* is the cause of sponge fisherman's disease.[33] This anemone lives at the base of sponges sought by commercial fishermen. When they harvest or sort the sponges with their bare hands or forearms, they are likely to come into contact with the tentacles of *Sagartia*. Itching and burning occur at the sting site within minutes, accompanied by erythema, edema, and vesicles.[33]

Treatment of sea anemone stings is similar to that of jellyfish envenomations (see Prevention and Treatment of Jellyfish Stings).[55] The tentacles should be removed carefully.[33] Both vinegar and Stingose (an aqueous solution of 20 percent aluminum sulfate and 11 percent surfactant) have been suggested for application to neutralize the sites of anemone stings.[56] Sea anemone sting sites often heal slowly and may require treatment with antibiotics.

INJURIES CAUSED BY FIRE CORAL AND CORAL CUTS Corals are colonial organisms belonging to the phylum Cnidaria. Coral injuries may be caused by nematocyst stings or lacerations. Both injuries may occur at the same time and may be complicated by foreign-body reactions, bacterial infections, and localized eczematous reactions. For most true corals nematocyst envenomation is a relatively innocuous experience, resulting in mild pruritic erythema that requires little if any treatment. Calamine lotion or antipruritic lotions may bring relief.[57]

In contrast to the stings of true corals, the sting of the fire coral, *Millepora alcicornis*, is quite painful, as many scuba divers and snorkelers from the Florida Keys to the Caribbean will attest (Fig. 209-14). The wet mucous membrane or slime surrounding the organism contains numerous nematocysts that readily discharge

▲ **FIGURE 209-13** Delayed-type hypersensitivity reaction to a presumed sea anemone sting. This 11-year-old girl stepped into a hole while wading in shallow waters on the South Carolina coast. She experienced an immediate burning pain with erythema and swelling of both lower legs that subsided within a day. Several days later she developed a pruritic linear eruption. A diagnosis was made of a delayed-type hypersensitivity reaction that developed in the sting site and corresponded with the tentacle marks from what was presumed to be a sea anemone envenomation.

▲ **FIGURE 209-14** The mustard-colored finger-like outcropping in the upper left quadrant of this formation of coral and hydroids is a typical example of fire coral.

on contact with the skin, causing immediate burning and stinging pain. Within 1 to several hours a pruritic erythematous papular eruption appears, which in severe cases may become pustular and, in rare cases, may progress to necrosis and eschar formation.[57] Lesions heal in 1 to 2 weeks, often with post-inflammatory hyperpigmentation. A delayed and persistent allergic contact dermatitis has also been reported to occur from a fire coral sting in the Red Sea.[58]

Fire coral stings should be rinsed with seawater to remove undischarged nematocysts. The sting area can then be compressed with either 5 percent acetic acid (vinegar) or 40 percent to 70 percent isopropyl alcohol for 15 to 30 minutes or until the pain is relieved.[36,59] Seawater compresses, hot to the point of tolerance, are also reported to inactivate the toxin. A topical steroid cream or ointment may relieve pruritus and promote healing.

Coral cuts, lacerations caused by the razor-sharp exoskeletons of coral, are notorious for their slow healing and propensity for secondary infection.

Treatment of coral cuts should begin with vigorous cleansing of the wound with soap and water with a soft brush or rough towel, followed by copious irrigation with saline to remove foreign bodies. If the wound is extensive, local anesthesia may be required to allow adequate cleansing, exploration, and débridement and to achieve good hemostasis. Hydrogen peroxide washing of the wound before dressing it is recommended.

The decision whether to perform primary closure of a coral cut wound or to allow it to heal by secondary intention depends on the location of the wound, the degree of tissue trauma at the wound margins, and the likelihood of subsequent infection. Tape stripping is preferable to suturing of leg wounds, because sutured leg wounds have a high chance of abscess formation.

Dermatitis from Sponges

Sponges are members of the phylum Porifera, class Desmospongiae. They are simple multicellular animals that live attached to the sea bottom. Sponges grow by forming a series of hollow-centered branching tubes composed of a fibrous material called *spongin*, which contains spicules of calcium carbonate or silica.[33,60,61] Spicules of certain species of sponges are capable of penetrating the skin, causing a localized irritant or foreign-body reaction. Treatment of sponge spicule dermatitis involves tape stripping of the affected area.

At least 13 species of sponges can cause a toxic dermatitis. Of these, the most commonly encountered are the West Indian and Hawaiian fire sponge, *Tedania ignis*; the poison bun sponge, *Fibula nolitangere* (Fig. 209-15); and the red sponge, *Microciona prolifera*, found in the northeastern United States.[62] These creatures are covered by a surface secretion, or slime, that produces an irritant or toxin-induced dermatitis when contacted by bare skin.[61]

Symptoms of itching, prickling, stinging, or burning appear within minutes of exposure and are followed within a few hours by pain, swelling, and stiffness. If the fingers are involved, they often become immovable within 24 hours. The first cutaneous sign of sponge poisoning is local erythema, which progresses to a papular, vesicular, or bullous eruption with weeping of a serous or purulent fluid.[61,62] Desquamation of the site occurs within several days. Erythema multiforme and anaphylactoid reactions have been reported in highly sensitized individuals.

Treatment of sponge dermatitis is similar to that of severe poison ivy.[62]

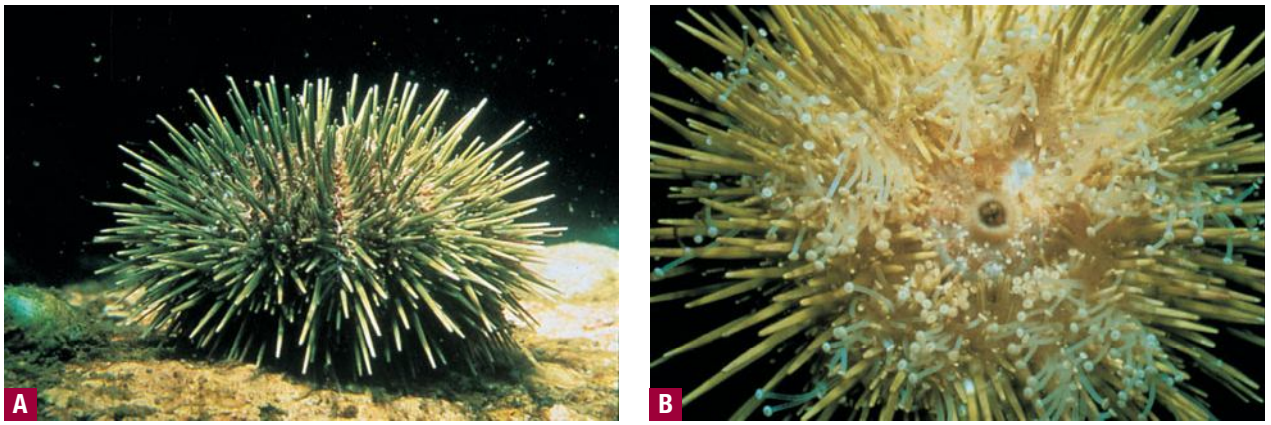
Injuries Caused by Echinoderms: Sea Urchins, Starfish, and Sea Cucumbers

SEA URCHINS Sea urchins are spiny creatures that belong to the phylum Echinodermata, class Echinoidea. They are encased in a fragile, roughly spherical, calcareous shell, which is protected by a formidable array of mobile spines and pincer-like organs known as *pedicellariae*[63,64] (Fig. 209-16).

Bathers, surfers, divers, and fishermen are all at risk for sea urchin injuries.

Encounters with sea urchins can result in both immediate and delayed reactions. Immediate reactions are usually localized and are initially manifested by a severe burning pain at the wound site, which quickly becomes red and swollen and may bleed profusely. There may be a black or purple discoloration at the site of the spine penetration due either to retained spines in the wound or to a tattoo-like effect from dye released by spines that have exited intact, but this discoloration will likely disappear

◀ **FIGURE 209-15** The poison bun sponge, *Fibula nolitangere*, can cause a severe irritant or toxin-induced contact dermatitis.



▲ **FIGURE 209-16** Lateral (**A**) and ventral (**B**) views of a sea urchin demonstrate this animal's protective spines and venomous pedicellaria underneath. (Used with permission from Marty Gilman, Worcester, MA.)

within 48 to 72 hours.[59] Paresthesias may develop at the wound area. Systemic symptoms are not common but can occur in injuries due to particularly venomous species. Symptoms may include nausea, syncope, paresthesias, ataxia, muscle cramps, paralysis, and respiratory distress.[62]

Delayed-type hypersensitivity reactions may occur with erythema and intense pruritus days after the initial injury.[65] In one of these cases, the diagnosis was confirmed by patch testing with extracts of the ground sea urchin spines.[66] Nodular reactions are localized to the area of spine penetration and are not usually painful. Nodules may take on colors from the dye in the spines[63] and may have a central umbilication or a keratotic surface[63] (Fig. 209-17).

The diffuse form more commonly involves the fingers or toes and is manifested by a fusiform swelling of the affected digit with accompanying pain and loss of function.[62,63] In addition to joint synovitis and arthritis, osteoarticular complications of sea urchin spine penetration may include tenosynovitis with or without destruction of the underlying bone, fasciitis, and bursitis.[67] Sea urchin spine wounds may also cause direct mechanical injuries to nerves and may be complicated by secondary infection.

Initial first aid for the pain from immediate reactions is to soak the affected area in hot water [43°C to 46°C (110°F to 115°F)] for 30 to 90 minutes until maximal relief is obtained. Infiltration of the wound site with 1 percent to 2 percent lidocaine without epinephrine may be required in some cases to produce significant pain relief.[70] Spines protruding from the wound may be carefully removed. They are very fragile, however, and it is difficult to extract the entire spine intact. Tumescence of the skin with a local anesthetic may allow superficially imbedded spines to be extracted when radiographs demonstrate no evidence of joint or bony impingement.[64] More invasive attempts at spine removal should not be made without the benefit of aseptic surgical facilities and radiographs to confirm the spine locations. Removal of the spines may be aided by the use of an operating microscope. Antibiotics are indicated for secondary infections, and tetanus prophylaxis should be given if indicated.

▲ **FIGURE 209-17** **A** and **B.** Nodular reactions to imbedded sea urchin spines. (Used with permission from Karen Rothman, MD.)

STARFISH Certain species of starfish may produce puncture wound injuries similar to those caused by sea urchins. The crown-of-thorns starfish, *Acanthaster planci,* accounts for most severe starfish envenomations.[62] The ice pick–like spines of *A. planci,* which may reach 4 to 6 cm in length, are covered with a thin skin and glandular tissue that produce a poisonous slime.[71] The resulting wound is quite painful and may be accompanied by numbness and paresthesias. Systemic symptoms including nausea, vomiting, and muscle weakness are infrequent and short lived.[62] Fragments of spines and their surrounding integument may become imbedded in the wounded area, resulting in granulomatous reactions.

Treatment is similar to that of sea urchin wounds.

SEA CUCUMBERS Sea cucumbers are sausage-shaped, bottom-feeding echinoderms that can produce a papular contact dermatitis by means of a toxic liquid substance, known as *holothurin,* that is secreted from their body walls.[33] Conjunctivitis, even blindness, can result from corneal involvement if the toxin comes in contact with the eyes.[62] Prevention of sea cucumber dermatitis involves protecting the skin and eyes from contact with these creatures and educating children and curious divers about the risk of handling them. Treatment consists of washing the affected area with soap and water to remove the toxin and then treating as for a mild contact dermatitis.

Dermatitis and Bites from Marine Worms

BRISTLEWORM DERMATITIS Bristleworms are multisegmented marine worms of the phylum Annelida, class Polychaeta (which means "many bristles"; Fig. 209-18). Each segment of the worm is armed with rows of silky or bristle-like, hollow, venom-filled setae that can easily penetrate and break off in the unprotected skin of a victim as do cactus spines.[71] Contact with the bristleworm results in an erythematous papular or urticarial eruption at the site, accompanied by symptoms of paresthesias, intense itching, or burning pain.[33,71] The bristles are too small and fragile in most cases to be removed with a forceps; however, tape stripping with cellophane adhesive tape can be effective. After the setae have been removed, the application of ammonia soaks or alcohol or water compresses may bring symptomatic relief.

◀ **FIGURE 209-18** *Hermodice carunculata*, the West Indian bristleworm, can inflict a painful wound with its hollow, venom-filled bristle-like setae. (Used with permission from Marty Gilman, Worcester, MA.)

LEECH BITES Leeches are another class of segmental worms whose bites may be encountered in freshwater or saltwater as well as on land. Although freshwater leeches are capable of attaching painlessly to their human hosts, saltwater leeches produce bites with pain similar to that of a bee sting. Leeches inject a powerful anticoagulant, hirudin, into the wound, as well as other antigenic substances that are capable of eliciting allergic reactions (including anaphylaxis) in sensitized individuals. Local symptoms of leech bites include bleeding from the puncture marks, pain, swelling, redness, and severe pruritus; urticarial, bullous, or necrotic reactions may occur in sensitized persons.[33]

Severe ulcerations may result if the leech is removed forcibly and its mouth parts are left behind in the bite site. Leeches must be induced to fall off by applying a noxious agent (such as alcohol, vinegar, brine, or a match flame) to their site of attachment.

CERCARIAL DERMATITIS (CLAM DIGGER'S ITCH) Cercarial dermatitis, also known as *schistosome dermatitis* or *swimmer's* or *clam digger's itch,* is an acute pruritic eruption resulting from penetration of the skin by the cercarial forms of certain parasitic flatworms of the family Schistosomatidae.

Symptoms of cercarial dermatitis begin with urticaria-like lesions and a prickling sensation of the skin, which lasts about half an hour after exposure to cercaria-infested waters. Severe pruritus of the affected area occurs 10 to 12 hours later. Within 24 hours, erythematous papules appear that may progress to vesicles and later to pustules. Pain and swelling of the area accompanies the intense itching, which usually peaks in 48 to 72 hours. Headache, fever, and superinfection with lymphangitis are occasionally present.

In the Great Lakes region, several species of schistosome cercariae that cause swimmer's itch have been reported, and many other such species have been discovered throughout the world in both freshwater and saltwater.[72,73] A severely disabling form of cercarial dermatitis affects the paddy workers and rice farmers of the Far East. Cercarial dermatitis has also been described in individuals exposed to shallow coastal waters, notably on Long Island Sound where the condition affects clam diggers, giving rise to the name, *clam digger's itch* (Fig. 209-19). There is one reported case of cercarial dermatitis occurring on the hands and arms of a patient after he cleaned the aquarium in which he kept native water snails.[74]

Humans are accidental hosts in the life cycle of dermatitis-producing schistosomes.

The differential diagnosis of cercarial dermatitis includes insect bites from

▲ **FIGURE 209-19** Intensely pruritic papulovesicles suggestive of a severe reaction to flea bites in a patient with clam digger's itch. The left hand, which was not in the water and was holding the pail for collecting the clams, was spared.

chiggers, mosquitoes, and fleas; contact dermatitis from poison ivy; and the stings of other marine coelenterates. In Africa, Asia, South America, and Puerto Rico, swimmer's itch must be distinguished from the dermatitis associated with human schistosomiasis, which produces an eruption with very similar but milder and more transient symptoms.[75] Swimmer's itch must also be distinguished from sea bather's eruption (SE), which is discussed in the next section.

Prevention of cercarial dermatitis in waters where swimmer's itch is known to be a problem is difficult. Coating the skin with petrolatum and various chemical repellents has been tried, but the effectiveness of these methods remains unproven. Clothing barriers may be of some help.

Treatment of cercarial dermatitis is largely symptomatic. In mild cases, antipruritic or drying lotions, oatmeal or starch baths, and antihistamines may alleviate pruritus. Aspirin may be helpful for the pain and swelling, and a bedtime sedative may be required to allow the patient much-needed sleep. Proper washing and hygiene should be maintained to prevent bacterial superinfection. In severe cases, potent topical glucocorticoids and occasionally systemic glucocorticoids may be required.

Sea Bather's Eruption

SE, also known as *marine dermatitis* and often misnamed *sea lice infestation*, is an acute dermatitis that begins shortly after bathing in seawater. SE is often confused with swimmer's itch (cercarial dermatitis, see previous section), not only because they both occur after exposure to water but also because the common names of these two conditions are easily confused. For many years, the cause of SE remained a mystery, but it is now known that the responsible agents in at least two types of SE are the larval forms of marine coelenterates. In waters off the coast of Florida and in the Caribbean, the tiny larvae of the thimble jellyfish, *Linuche unguiculata*, are to blame.[76] Off the coast of Long Island, New York, researchers found that the larval forms of the sea anemone *Edwardsiella lineata* were responsible for the eruption.

In addition to having a different etiology, SE can be distinguished from cercarial dermatitis by several other characteristics: SE primarily involves areas of the body covered by bathing suits from which water evaporates slowly, as opposed to uncovered areas as is typical of swimmer's itch. Most symptoms are not noted until the bather has left the water (although some of those affected have complained of a prickling sensation while still in the water).

▲ **FIGURE 209-20** Sea bather's eruption in a young girl after a swim at a Florida beach. (Used with permission from Karen Rothman, MD.)

The eruption is caused by minute stings from the nematocysts of the coelenterate larvae, which become trapped underneath swimwear or may adhere to hairy areas of the body. In addition to SE after contact with the larvae, which are most abundant in May and June, swimmers and bathers may also develop SE after contact with the other two free-swimming stages of *L. unguiculata*, the ephyrae and medusae stages.[77]

The lesions begin within 4 to 24 hours after exposure as erythematous macules, papules, or wheals that may itch or burn (Fig. 209-20).[33] These lesions may progress to vesiculopapules, which crust over and heal in 7 to 10 days. Associated systemic symptoms may include chills and a low-grade fever as well as nausea, vomiting, diarrhea, headache, weakness, muscle spasms, and malaise. Febrile and systemic symptoms are more common in children and adolescents.[78] In the presence of such constitutional symptoms, caregivers who fail to recognize the pattern of the eruption or who fail to take a history of exposure to saltwater may mistakenly make the diagnosis of a viral syndrome.

In waters along the coast of south Florida, the season for SE is between March and August with a peak in May. The incidence among bathers during May and June 1993 in Palm Beach County was reported to be 16 percent.[78] The strongest risk factor for developing SE is a previous history of the condition, which is consistent with the theory that SE represents a hypersensitivity response to the nematocyst stings. Other risk factors include age younger than 16 years and surfing. Showering with swimwear removed was found to be a protective measure.[78]

TABLE 209-5
Prevention of Seabather's Eruption

1. Bathers should remove their swimwear and shower as soon as possible after leaving the water. Because fresh water may cause discharge of the nematocysts, it is important that the suits be removed before showering begins.
2. Bathing suits should be rinsed with soap and water and heat dried, because the eruption can recur when the suit is air dried.
3. T-shirts should not be worn in the water. Women may consider wearing a two-piece suit to reduce the surface area under which larvae may be trapped.
4. Whole-body Lycra swimsuits or wetsuits with snug-fitting collars and cuffs may be protective, but the eruption may still occur along the collar or cuff edges.
5. Highly sensitized individuals should avoid swimming in infested waters during outbreaks of seabather's eruption.

Prevention of SE includes the measures listed in Table 209-5. Treatment of SE is symptomatic and includes the use of antipruritic lotions, colloidal baths with starch or oatmeal, antihistamines, and topical glucocorticoids. Severe unremitting cases may warrant systemic glucocorticoid therapy.[76] Secondary bacterial infections may complicate the condition and should be diagnosed and treated appropriately.

Injuries Caused by Mollusks

CONE SHELL ENVENOMATIONS Cone shells are univalvular gastropods whose ornate cone-shaped shells are highly prized by shell collectors and divers. A number of species have a highly developed venom apparatus that can inflict a lethal sting. Most of the dangerous cone shell species are found in the shallow waters of the Indo-Pacific. Cone shells are carnivorous. They live on the ocean bottom and, depending on the species, may hunt worms, other mollusks, or fish. Cone shells kill their prey by means of a spear-like venomous radular tooth that is thrust out from the animal's proboscis. Cone shell venom contains several different kinds of neurotoxins, and death may result from respiratory paralysis. There is so far no antivenin for cone shell toxin, and mortality rates after envenomations from

the more dangerous species (*Conus geographicus* and *C. magus*) may be as high as 15 percent to 20 percent.[33]

Injuries from cone shells are of the puncture wound variety. The degree of pain is variable, ranging from a mild stinging sensation, similar to that of an insect bite, to excruciating pain. Early symptoms may include edema, ischemia, numbness, and paresthesias of the wound site. Paresthesias may become widespread, with the lips and mouth commonly affected.[33,62] Localized muscular paralysis may progress to generalized weakness or paralysis with eventual respiratory distress and cardiopulmonary failure. Neurotoxic symptoms that indicate severe envenomation include diplopia, blurred vision, aphonia, dysphagia, and coma. Rare cases of disseminated intravascular coagulation have been reported after cone shell envenomation.

Great care must be exercised in handling live cone shells. Thick protective gloves should be worn, and the soft under portion of the animal should be avoided. Cone shells should never be placed in pockets of clothing or swimwear, because they have been known to sting through clothing.[70]

Treatment of cone shell envenomations is supportive. The victim should be kept at rest and the sting area kept dependent and immobilized. A compression dressing should be applied to occlude lymphatic-venous, but not arterial, flow.[70] Local suction may be helpful if it can be applied immediately to the wound site with a plunger device, such as the Extractor Vacuum Pump (Sawyer Products, Safety Harbor, Florida).

OCTOPUS BITES Octopuses are an advanced group of mollusks belonging to the class Cephalopoda. The octopus bites with a parrot-like chitinous beak located on the ventral side of the head in the middle of its eight tentacles (Fig. 209-21). Species of octopi range in size from a few centimeters to 1 to 2 m in diameter.[80] They are shy and reclusive creatures that tend to avoid encounters with humans; however, bites can occur when curious divers, fishermen, or beachgoers encounter these animals and handle them carelessly. Most octopus bites are not life-threatening to humans. The bite site may be immediately painful, as after a bee sting, and is recognized by the presence of two small puncture wounds, which may bleed profusely.[70] Symptoms from octopus bites are usually mild and transient and consist of redness, swelling, and itching.[80]

◀ **FIGURE 209-21** Ventral view of the underside of an octopus exposing the animal's centrally located mouth and parrot-like beak. (From Fulghum DD: Octopus bite resulting in granuloma annulare. *South Med J* **79**:1434, 1986, with permission.)

The most dangerous species of octopus, the Australian blue-ringed octopus, *Hapalochlaena maculosa*, is found in Australian coastal waters. Mortality rates after bites from *H. maculosa* may be as high as 25 percent. *H. maculosa* produces a toxin in its salivary glands that is introduced into the bite site by the animal's powerful beak and contains a fraction identical to tetrodotoxin; this toxin blocks peripheral nerve conduction and results in paralysis of the victim with subsequent respiratory failure. The bite of the blue-ringed octopus may or may not be painful, so that victims may not realize they have been bitten until neurologic symptoms develop.[62]

There is no antivenin for bites of *H. maculosa.* Treatment is supportive and similar to that recommended in the previous section for severe cone shell envenomations.

Injuries Caused by Venomous Fish Spines

Ichthyoacanthotoxicosis is the proper term for envenomations as a result of puncture wounds or lacerations inflicted by the spines of venomous fish. There are more than 200 species of venomous fish in the world that can cause injury to humans.[62] The most notorious of these species are the stingrays, catfish, lionfish, scorpionfish, stonefish, weeverfish, toadfish, and spiny dogfish. All of these fish have in common a venom apparatus consisting of a single spine or multiple spines, in various locations, which are covered by an integumentary sheath enclosing various forms of venom glands. When the spine of the animal penetrates the victim, the sheath is torn and the venom glands release their toxins into the wound. The toxins from some of these fish may remain potent for 24 to 48 hours after the death of the fish.[81]

STINGRAYS Stingrays are one of the most common causes of venomous fish stings confronting humans, with as many as 1500 to 2000 stingray attacks reported each year in the United States alone.[71,82] Rays are grouped into one of four categories; gymnurid (butterfly rays), urolophid (round stingrays), myliobatid (bat or eagle rays), and dasyatid (proper stingrays). The groupings are based on their relative stinging ability, which depends on the size, number, and location of the caudal stinging appendages. The most dangerous group, the dasyatid or true stingrays, have the largest spines located further out on their tails, which makes theirs the most potent striking weapons. The spines have retroserrated teeth, so that removal is difficult (Fig. 209-22).

Most stingray injuries occur when bathers, waders, or fishermen accidentally step on rays as they lie partially covered with sand in shallow waters.[83,84] Severe lacerations and puncture wounds are inflicted by the ray as it defensively whips its tail upward and forward when stepped on or threatened[83,84] (Fig. 209-23). The majority of wounds, therefore, are located on the dorsum of the foot or lower leg. Penetrating wounds to other locations have occurred to fishermen stung while attempting to remove rays from their lines or nets.

CATFISH Both freshwater and saltwater catfish are armed with stout, sharp spines located immediately in front of the soft rays of their dorsal and pectoral fins. Catfish defensively lock these spines into an extended position when they are handled or threatened. Bathers may sustain stings on their feet or legs if they step on a catfish, but most catfish stings involve the hand or upper extremity of fishermen or seafood processors.[86] To prevent these injuries, it has been suggested that the offending

▲ **FIGURE 209-22** A close-up view of a stingray stinger without its outer membrane and venom glands, demonstrating the retroserrated spine. (Used with permission from David Fulghum, MD.)

spines be removed with a pair of pliers before cleaning of the fish is attempted.

Swimmers and bathers in the Amazon River are at risk for urologic injuries if they encounter a very small species of catfish called the *candiru*, which has the ability to enter the human urethra. Barbs on the head of this fish prevent it from swimming backward out of the orifice, and surgical intervention is often required to extract the fish.

SCORPIONFISH Scorpionfish, family Scorpaenidae, are divided into three main groups on the basis of their stinging apparatus. All have venomous spines of varying sizes and toxicity, which may be found in dorsal, pelvic, and anal locations, depending on the species.

Scorpionfish, genus *Scorpaena*, have stings that are of intermediate severity. They are bottom dwellers with superior camouflage abilities that allow them to blend in almost invisibly with their surroundings (Fig. 209-24). Their spines are long and heavy and have moderate-sized venom glands.

Stonefish, genus *Synanceja*, are the most dangerous members of the scorpionfish family. They live in shallow waters, sometimes partially buried in sand or mud, or in holes of rocky shoals, reef areas, or tidal pools.[71] Injuries occur when a wader steps on the erect venomous dorsal spine that the stonefish raises in defense. Stonefish spines are short and thick and have very large and well-developed venom glands.[54] The wounds caused by stonefish are quite severe and may be fatal. A stonefish antivenin is available.

WEEVERFISH In European coastal waters, the weeverfish is one of the most common and serious causes of venomous fish spine injuries.[88] These fish are equipped with between five and eight venomous dorsal spines and two venomous opercular spines (one on each side of the head near the gill plate).[89] Waders and bathers are at risk when they step on weeverfish that lie partly buried in mud or sand in shallow waters.

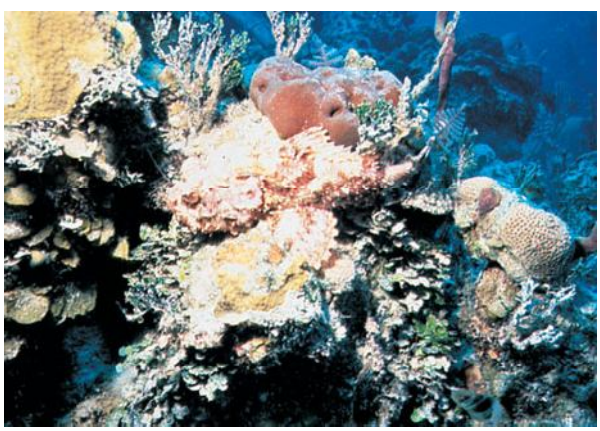
▲ **FIGURE 209-23** Stingrays reflexively swing their barbed tails up when stepped on, causing painful lacerations and puncture wounds. (The leg used for this photograph was a prosthesis; the stingray was alive.) (Used with permission from David Fulghum, MD.)

LOCAL AND SYSTEMIC SYMPTOMS OF FISH SPINE ENVENOMATIONS The toxicity of a given venomous fish sting depends on a number of factors, including the species of fish involved, the location and severity of the wound, the amount of venom released, and the first aid and subsequent medical care provided to the victim. In general, these wounds produce pain out of proportion to the apparent severity of the injury. The pain is immediate and intense. In the case of scorpionfish stings, the pain may be so severe as to cause the victim to thrash about wildly, scream, and finally lose consciousness.

Initially, the sting site may appear pale or cyanotic. The area around the wound may be anesthetic or hyperesthetic.[54] Erythema and edema soon develop, giving the appearance of a cellulitis. Vesicles may form. In severe stingings, especially those caused by stonefish, the wounded area may become indurated and develop areas of ischemic necrosis with subsequent sloughing and ulcer formation.

Systemic effects from toxic fish spine envenomations may range from mild to severe, depending on the species involved and the amount of venom entering the wound. They can include headache, nausea, vomiting, diarrhea, abdominal cramps and pain, fever, local lymphangitis and lymphadenitis, joint aches, muscle weakness, diaphoresis, peripheral neuropathy, limb paralysis, restlessness, delirium, seizures, cardiac arrhythmias, myocardial ischemia, pericarditis, hypotension, and respiratory distress, and can lead to death.[79,88,90,91]

PREVENTION Prevention of toxic fish spine wounds begins with knowledge of and appreciation for the various venomous species that may be encountered in a given area. Waders and bathers should shuffle their feet to scare away



▲ **FIGURE 209-24** *Scorpaena plumieri*, a species of scorpion fish, is found in the waters of the West Indies. Its camouflage abilities are exceeded only by its painful sting.

and avoid stepping on rays or scorpionfish. Fishermen must exercise care when removing rays or catfish from their fishing lines or when cleaning fish with venomous spines. Fish hobbyists and divers should wear protective clothing and avoid handling venomous species.

TREATMENT Puncture wounds and lacerations from venomous fish spines should be irrigated immediately with sterile saline or water, if available, and with seawater as a last resort.[70] The wounded area should then be soaked as quickly as possible in hot (not scalding) water of approximately 43°C to 46°C (110°F to 115°F) for 30 to 90 minutes or until maximal pain relief is achieved. Hot soaks may be repeated if the pain returns. Because the wound or extremity may be partially anesthetic, the person administering first aid must test the water's temperature for the victim.[84] One source of hot water that is often overlooked and may be useful in an emergency is hot seawater from a boat motor's cooling system.[84]

Local infiltration of the wound with 1 percent to 2 percent lidocaine without epinephrine may bring about significant pain relief and allow exploration of the wound after radiographs have been obtained to locate retained portions of spines.[59,71,84] Longer-acting anesthetics such as procaine and bupivacaine may be chosen to provide a longer period of pain relief. The wound should be thoroughly cleaned to remove any remnants of integumentary sheath. Cleansing with a toothbrush and a solution of hexachlorophene in 70 percent alcohol has been recommended.[78] Abdominal and thoracic wounds and deep wounds to the hands, feet, or fascial compartments of the legs should be explored in the operating room.[71] Débridement of necrotic tissues may be required at the time of exploration, and sequential débridement may be necessary. In general, these wounds should be left open or closed loosely with tape or suture to allow for adequate drainage and to prevent abscess formation.

Tetanus prophylaxis should be administered if indicated, and antibiotics are recommended if the wound is more than 6 hours old, is extensive, or involves deep puncture injuries to the hand or foot.[71] The choice of antibiotic should be based on the bacteriology of the marine environment in which the wound occurred and, subsequently, on results of deep wound or tissue cultures. Empiric antibiotic therapy for infections of wounds occurring in saltwater should include coverage for *Vibrio* species. Before final wound culture results are known, initial choices of parenteral antibiotics include intravenous ciprofloxacin, imipenem-cilastatin, cefotaxime, ceftazidime, gentamicin, tobramycin, or trimethoprim-sulfamethoxazole (see also Chaps. 183 and 184).

Stonefish stings complicated by severe reactions may be treated with antivenin by slow intravenous infusion. Antivenin is not usually required for the stings of lionfish and other species of scorpionfish except for stonefish.[71] Stonefish antivenin is available from the Australian Commonwealth Serum Laboratory, Melbourne, Australia.

▲ **FIGURE 209-25** Moray eel bites are uncommon, but their incidence has increased because divers feed these animals at popular dive sites. (Used with permission from Marty Gilman, Worcester, MA.)

Fish Bites

There are many species of fish whose bites are dangerous to humans. Among the best known are the sharks and barracudas, whose bites may cause severe injuries.

Although they are well publicized by the news media, shark attacks are relatively rare events. The average number of shark attacks worldwide is between 30 and 100 annually.[96] Only 32 of the 350 known species of sharks have been reported to attack humans. Most shark attacks involve surfers, scuba divers, and swimmers. Because sharks are attracted to bright or shiny objects, as well as to those with contrasting colors, these items should not be worn in the water. Sharks are also attracted by any sort of blood in the water; therefore, women who are menstruating should refrain from water sports in areas in which sharks may be prevalent, and no one should swim with an open bleeding wound. Spear fishermen should never tie their catch to themselves, and they should place their catch in the dive boat as soon as possible. Although most shark bites are not life-threatening, more severe attacks may cause extensive soft-tissue loss with massive hemorrhage, which, in the worst cases, can result in amputation of a limb or death.[97,98]

Barracuda attacks are even rarer than shark bites. They tend to occur in turbid waters where these predators may mistake jewelry or other brightly colored objects worn by bathers for the baitfish on which they feed. Barracuda bites typically produce straight or V-shaped lacerations.

Divers and aquarium hobbyists must be careful when feeding or handling moray eels, which have powerful jaws and knife-like teeth. Although they are not considered venomous by most sources, they can produce deep puncture wounds and lacerations[70] (Fig. 209-25). When biting, moray eels tend to lock onto their prey; decapitation of the eel or disarticulation of its jaw may be required to release the victim.[99] As with all deep puncture wounds or lacerations, victims of moray eel bites should receive tetanus prophylaxis. Empiric antibiotic therapy for prophylaxis or treatment can include ciprofloxacin or cefuroxime for coverage of *Vibrio* or *Pseudomonas* species.[100]

WATERBORNE INFECTIONS

A variety of infections may result from exposures to aquatic environments. Pathogenic organisms may be actively introduced into the bite, sting, or laceration wounds caused by marine life; preexisting wounds may be passively infected when exposed to contaminated waters. *V. carchariae*, a halophilic (saltwater-loving) Gram-negative bacillus, was reported as the cause of a wound infection after a shark bite.[103,104] Table 209-6 lists those organisms commonly associated with waterborne in-

TABLE 209-6
Wound Infections Associated with Waterborne Organisms

ORGANISM	CLINICAL FEATURES
Aeromonas hydrophilia	Cellulitis (may be bullous), fasciitis, myonecrosis, bacteremia.
Edwardsiella tarda	Cellulitis, abscess, osteomyelitis, bacteremia.
Erysipelothrix rhusiopathiae	Slowly progressive cellulitis without adenopathy or lymphangitis, almost always involving the hand; septic arthritis; subacute bacterial endocarditis.
Mycobacterium balnei or *marinum*	Swimming pool granuloma; fish fancier's finger; chronic cellulitis and culture-negative ulcers; often the primary lesion is on the hand and then a series of lesions develop in draining lymphatics.
Pfisteria piscicida	Raw, red pock-marked lesions in fish in polluted waterways; in humans, rashes, respiratory problems, and memory deficits.[92]
Protothecosis	Papular or eczematoid dermatitis in immunosuppressed patients; localized infection of the olecranon bursa.
Pseudomonas species	Trench foot; Gram-negative toe web space infections; swimmer's ear; hot tub folliculitis.
Streptococcus iniae	Cellulitis and bacteremia after skin injuries during the handling of fresh fish raised by aquaculture.
Vibrio vulnificus, other *Vibrio* sp.	Cellulitis, sometimes with bulla formation; may progress to septicemia, especially in alcoholics, diabetics, and immunosuppressed patients; metastatic cellulitis, meningitis, and death may result from fulminant infections.

fections (see also Chaps. 183 and 184). A host of other agents, such as *Streptococcus* and *Staphylococcus* sp., *Bacteroides fragilis*, *Clostridium perfringens*, *Escherichia coli*, *Salmonella enteritidis*, marine *Vibrio* sp., *Chromobacterium violaceum*, and *Chlorella*, also require consideration when dealing with infections associated with aquatic settings.[71]

CUTANEOUS MANIFESTATIONS OF SEAFOOD INGESTION AND SEAFOOD POISONING

Dermatologic reactions may appear after the ingestion of seafood. Urticaria, angioedema, and, rarely, leukocytoclastic vasculitis may occur in individuals sensitized to fish or shellfish. Many seafoods, such as kelp, contain large amounts of iodine, which may cause acneiform eruptions.

Scombroid food poisoning involves the ingestion of spoiled fish from the Scombroidae family of fish, such as tuna, mackerel, and bonita. If these fish are not kept cold enough after being caught, their flesh develops scombrotoxins as a consequence of the bacterial breakdown of histidine into histamine, saurine, and possibly other toxic by-products. These can cause striking erythema and flushing of the face, neck, and upper trunk, as well as pruritus and urticarial and angioedematous eruptions. Antihistamines can provide symptomatic relief in severe cases.

Ciguatera toxin, which is produced during blooms of toxic dinoflagellates, is incorporated into the marine food chain and concentrated in the flesh of a variety of fish. It is heat stable, and symptoms may occur after eating cooked or raw fish containing the toxin. Dermatologic symptoms of ingesting these fish may include generalized pruritus and diffuse erythematous macular and papular exanthems, which may progress to blister formation and desquamation.

CHAPTER 210

Arthropod Bites and Stings

Christopher J. Steen
Robert A. Schwartz

Arthropod bites and stings are a significant cause of morbidity worldwide. Although many arthropod attacks produce only mild, transient cutaneous changes, more severe local and systemic sequelae can occur, including potentially fatal toxic and anaphylactic reactions. Arthropods also serve as vectors for numerous systemic diseases. The medically significant classes of non-aquatic arthropods are Arachnida, Chilopoda, Diplopoda, and Insecta (Fig. 210-1).[1]

HISTOPATHOLOGY

Many arthropod bites produce a similar histologic reaction pattern. In the acute phase, there is a superficial and deep, perivascular and interstitial inflammatory infiltrate, which is characteristically wedge-shaped. The infiltrate is usually mixed in composition with an abundance of lymphocytes and eosinophils, although neutrophils and histiocytes can also be seen. Neutrophils may predominate in reactions to fleas, mosquitoes, fire ants, and brown recluse spiders. Over the most prominent superficial infiltrates, spongiosis can be seen, sometimes with progression to vesicle formation or epidermal necrosis. Older, excoriated areas are usually altered by the effects of scratching, with the development of parakeratosis, serum exudates, and a dermal infiltrate with neutrophils and more abundant lymphocytes. Although not commonly seen on histology, insects or insect parts, including burrowed scabies mites, eggs, feces, or the retained mouth parts of ticks, may be visible. Chronic lesions, which most often result when arthropod parts are retained in the skin, may take on a pseudolymphomatous appearance (see Chap. 147).

TREATMENT PRINCIPLES

The morbidity from arthropod bites and stings varies with the species inflicting the injury. Although species-specific clinical findings and treatment will be discussed in further detail, there are several general treatment principles that apply. Local wound care is essential following arthropod assault. Wounds should be cleansed and any remaining arthropod parts, including stingers, should be removed as soon as possible. Patient discomfort should be addressed and can involve a variety of treatment modalities, including the use of ice packs, application of topical corticosteroids and antipruritics, injection of local anesthetics, and, less frequently, the use of systemic analgesics. Supportive measures for systemic toxic and allergic reactions, including anaphylaxis, should be instituted when necessary. Secondary infections should be treated with appropriate antibiotics, and bites from several terrestrial arthropods species may require tetanus prophylaxis. Severe envenomation from particular species, such as the black widow spider, may require antivenin administration. Documented hypersensitivity to some species can be treated with desensitization immunotherapy. Awareness of the potential arthropod-borne illnesses spread by each species is also important.

DIFFERENTIAL DIAGNOSIS (Box 210-1)

ARACHNIDA

The class Arachnida contains three orders of medical significance: Araneae (spiders), Acarina (ticks and mites), and Scorpiones (scorpions). Arachnida are distinguished anatomically from other arthropods by a lack of wings or antennae and the presence of four pairs of legs and two body segments. Larval ticks, which only have three pairs of legs, are an exception to this rule (see Fig. 210-1).

Araneae

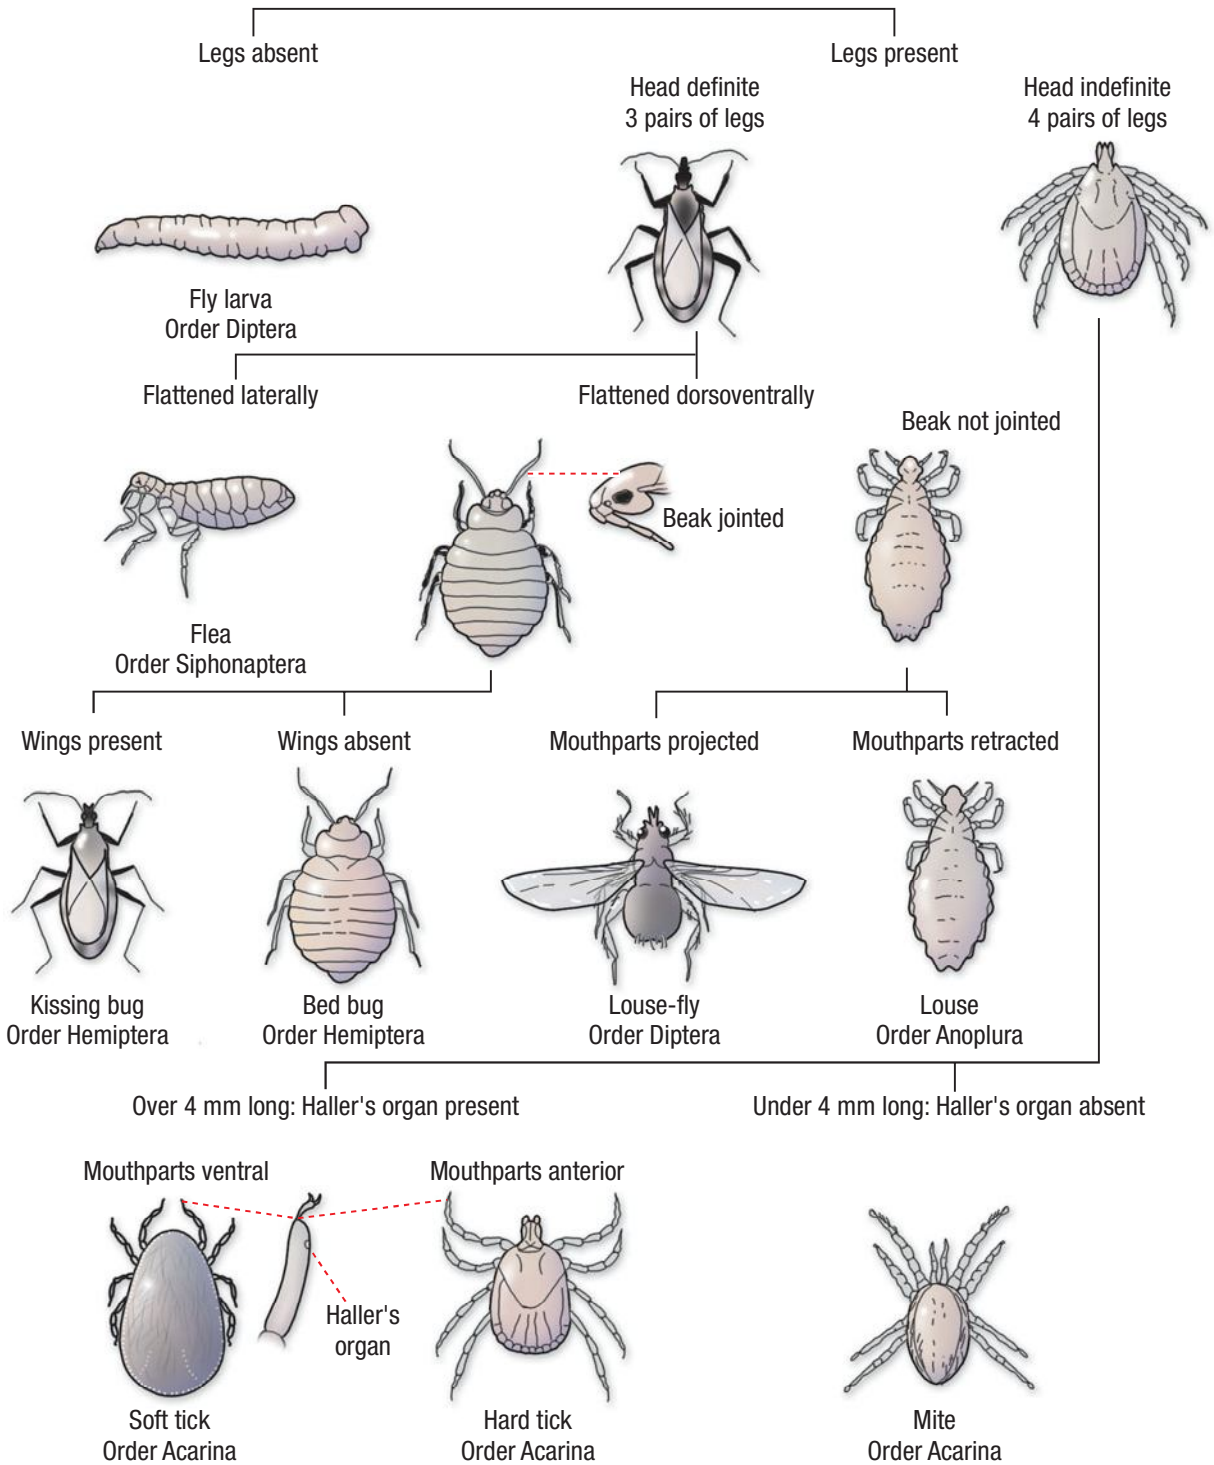
Spiders are carnivorous members of the animal kingdom that use webs and venom to capture and kill prey. Within the United States, three genera contain species whose bites are toxic to man: *Latrodectus*, *Loxosceles*, and *Tegeneria*. The American Association of Poison Control Centers reported over 15,000 spider bites in the United States in 2004.[2] In the same year, only one death was attributed to spider envenomation in the United States.

LATRODECTUS Members of the *Latrodectus* genus, or widow spiders, are often black in color and have a red, hourglass-shaped marking on their abdomens (Fig. 210-2). Although there are more than 20 species of widow spiders, *L. mactans*, the Southern black widow spider, is the most common and notorious in the United States and can be found in all but the most northern parts of the country. Other widow spiders encountered in the United States include *L. various* (Northern black widow), *L. hesperus* (Western black widow), *L. bishopi* (red-legged widow), and *L. geometricus* (brown widow). Members of the *Latrodectus* genus are non-aggressive, trapping spiders that spin webs in protected areas and await their prey. Human bites are often the result of accidental or deliberate provocation. Webs are typically found on the corners of doors and windows, underneath woodpiles, in garages and sheds, and on the undersides of eaves. Webs can also be found around outdoor toilet seats, a location that has led to bites on or near the genitalia.[3]

Clinical Findings. Bites of the black widow spider (*L. mactans*), which are often painful, usually only result in mild dermatologic manifestations. Within the first 30 minutes, localized erythema, piloerection, and sweating may appear at the wound site. A sensation of numbness or aching pain may develop shortly after the bite. Urticaria and cyanosis may occur at the bite site. Black widow venom contains the neurotoxin α-latrotoxin, which acts by opening ion channels at presynaptic

ARTHROPOD BITES AND STINGS AT A GLANCE

- Many arthropod species are capable of inflicting bites and stings on humans.
- Reactions to arthropod assaults can range from mild to life-threatening.
- Arthropods also serve as vectors for systemic diseases.
- The terrestrial arthropods of medical importance include the orders Arachnida (arachnids), Chilopoda (centipedes), Diplopoda (millipedes), and Insecta (insects).



▲ **FIGURE 210-1** Pictorial key to groups of human ectoparasites. (Used with permission from C. J. Stojanovich and H. G. Scott, U.S. Department of Health, Education, and Welfare, Public Health Service.)

nerve terminals, thereby causing an irreversible release of acetylcholine at motor nerve endings and catecholamines at adrenergic nerve endings.[4] Consequently, black widow bites may produce agonizing crampy abdominal pain and muscle spasm that may mimic an acute abdomen.[4] Other signs and symptoms include headache, paresthesias, nausea, vomiting, hypertension, lacrimation, salivation, seizures, tremors, acute renal failure, and sometimes, paralysis; fortunately, death is uncommon. Based on the spectrum of symptoms, black widow bite may be misdiagnosed as drug withdrawal, appendicitis, meningitis, or tetanus, to name a few.[4]

Management. Although many widow spider bites require only local wound care, more serious reactions may necessitate hospitalization. Those patients at increased risk for serious complications include the very young, very old, and those with underlying cardiovascular disease. Current treatments for black widow envenomation include intravenous calcium gluconate (10 percent), narcotic analgesics, muscle relaxants, and benzodiazepines.[5] *L. mactans* antivenin prepared from equine serum is also available. Additionally, there appears to be an effective cross-reactivity among antivenin for a number of other

Box 210-1

Differential Diagnosis of Arthropod Bites and Stings

- Black widow bite: Acute abdomen (appendicitis, etc.), meningitis, tetanus, drug withdrawal, acute renal failure, acute myocarditis, acute coronary syndrome, other arthropod bite
- Brown recluse bite: Hobo spider bite, chemical burn, Lyme disease, cutaneous anthrax infection, pyoderma gangrenosum, ecthyma, trauma, vasculitis, neoplasm, other arthropod bite
- Scorpion sting: Other arthropod bite, tetanus, botulism, Guillain-Barré, organophosphate toxicity, medication overdose
- Centipede bite: Other arthropod bite, cellulitis
- Millipede "burn": Contact dermatitis, conjunctivitis
- Insect bites (flies, fleas, bedbugs, kissing bugs): Other arthropod bites (scabies, lice), atopic dermatitis, contact dermatitis, papular urticaria, delusions of parasitosis
- Hymenoptera bite/sting: Other arthropod bite, anaphylaxis
- Lepidopterism: Other arthropod bite, contact dermatitis, atopic dermatitis, phytodermatitis

Latrodectus species.[6–8] The benefits of the antivenin in treating complications of widow bites should be weighed against the potential for allergic reaction to the antivenin. Patients should also be up to date on tetanus immunization.

LOXOSCELES Members of the *Loxosceles* genus, also called *recluse spiders* or *fiddleback spiders*, are non-aggressive spiders characterized by a dark brown marking on their cephalothorax in the shape of a fiddle or violin (Fig. 210-3). The brown recluse spider, *L. reclusa*, is the most well-known member of this genus and is most abundant in the American Midwest and Southeast. Other medically significant members of this genus include *L. deserta* (Desert recluse), *L. rufescens* (Mediterranean recluse), *L. kaiba* (Grand Canyon recluse) and *L. arizonica* (Arizona recluse). Recluse spiders are so named because they will often seek out shelter in undisturbed places such as closets, attics, and storage areas for bedding and clothing. Bites usually occur when the spider feels threatened or provoked, such as when someone tries to put on clothing that contains the spider.[1]

Clinical Findings. Bites of the brown recluse spider (*L. reclusa*) vary from mild, local reactions to severe ulcerative necrosis, a reaction known as *necrotic arachnidism*. After a bite, transient erythema may develop with the formation of a central vesicle or papule. The hallmark "red, white, and blue" sign of a brown recluse bite is characterized by a central violaceous area surrounded by a rim of blanched skin that is further surrounded by a large asymmetric erythematous area (Fig. 210-4A). In a small percentage of cases, the initial wound may progress to necrosis (see Fig. 210-4B), which usually begins 2 to 3 days after the bite, with eschar formation occurring between the fifth and seventh days.[9] Eventually deep ulcers develop (see eFig. 210-4.1 in on-line edition). The bite reaction may mimic pyoderma gangrenosum or erythema migrans of Lyme disease.[10] Cutaneous anthrax and chemical burns have been mistaken for a brown recluse spider bite.[11,12] The potential for misdiagnosis has led to the development of a sensitive enzyme-linked immunosorbent assay for *Loxosceles* species venom that may eventually be available for clinical application.[13]

▲ **FIGURE 210-2** Black widow spider with characteristic red hourglass marking on the underside of its abdomen.

▲ **FIGURE 210-3** Brown recluse spider with characteristic fiddle-shaped marking on cephalothorax.

Brown recluse venom contains a number of proteins, including sphingomyelinase D, esterase, hyaluronidase, and alkaline phosphatase, which all contribute to tissue destruction. Sphingomyelinase D, the major component of the venom, cleaves sphingomyelin to form cermade-1-phosphate and choline and also hydrolyzes lysophosphatidylcholine to produce lysophosphatidic acid.[14] Lysophosphatidic acid then triggers a pro-inflammatory response and causes platelet aggregation and increased vascular permeability.[14] Sphingomyelinase D is also capable of inducing complement-mediated hemolysis.[15] Systemic symptoms may develop within 1 to 2 days after envenomation and include nausea, vomiting, headache, fever, and chills. Rare but serious sequelae of brown recluse bites include renal failure, hemolytic anemia, hypotension, and disseminated intravascular coagulation.[16,17]

Management. General treatment measures for recluse bites include cleansing the bite site and the application of cold compresses. Patients may also require

▲ **FIGURE 210-4** **A.** Clinically typical brown recluse spider bite showing the "red, white, and blue" sign. **B.** Late brown recluse spider bite with overlying eschar.

analgesics to control pain. Antibiotics may be useful in reducing secondary bacterial infection of the wound site. Warm compresses and strenuous exercise should be avoided. Although *Loxosceles* antivenins have been developed and are frequently used in South America, there is little evidence to support their effectiveness, particularly against local cutaneous effects.[8] A number of treatment modalities have been suggested, including hyperbaric oxygen, dapsone, intralesional and systemic corticosteroids, colchicine, and diphenhydramine.[18,19] However, one study that used a rabbit model to compare dapsone, colchicine, intralesional triamcinolone, and diphenhydramine showed no effect on eschar size from any of these medications.[18] Necrotic wounds heal slowly, sometimes over many months, and may require surgical excision and reconstruction to close the resulting defect. Surgical interventions should be delayed until the wound has stabilized.

TEGENARIA *Tegenaria agrestis*, the hobo spider or "aggressive house spider," is the predominant cause of necrotic arachnidism in the Pacific Northwest of the United States and can be found in an area ranging from Alaska to Utah.[20] Although *Loxosceles* species are not typically found in the same geographic distribution, bites from hobo spiders are often mistaken for brown recluse bites. These spiders are brown in color with a gray herringbone pattern on the abdomen.[21] The hobo spider typically builds funnel-shaped webs in crawl spaces, basements, wood piles, and bushes. Most hobo spider bites occur from July to September when the more venomous male spiders are seeking mates.

Clinical Findings. The local cutaneous effects after envenomation by the hobo spider, which can range from mild to serious, are similar to those caused by the brown recluse.[22] The initial bite is often painless. Induration and paresthesia of the bite site may develop within 30 minutes. A large erythematous area may form around the site. Vesicle formation often occurs during the first 36 hours. Eschar formation may follow in severe cases, with necrosis and sloughing of the underlying tissue.

Management. Wounds usually heal within several weeks. The most common systemic symptom after a hobo spider bite is a severe headache, which can persist for up to 1 week.[23] Other symptoms may include fatigue, nausea, vomiting, diarrhea, paresthesias, and memory impairment. Although rare, death may ensue due to severe systemic effects, including aplastic anemia.[23]

TARANTULA Tarantulas are indigenous to certain regions of the United States and are also kept as exotic pets. Tarantulas are members of the family Theraphosidae and are hair covered and larger than many other types of spider, with leg spans of up to 12 inches reported in certain species. Unlike the other venomous spiders discussed, tarantula bites generally only produce mild local symptoms. However, more serious reactions can be caused by urticating hairs on the spider's abdomen. When threatened, tarantulas may rub their back legs together in a motion that flicks these hairs off. These hairs may become embedded in the skin or eyes. Cutaneous responses to the hairs range from mild, local pruritus to granulomatous reactions. Ocular sequelae from hairs embedded in the cornea range from conjunctivitis and keratouveitis to corneal granulomas and chorioretinitis.[24–27] Although cutaneous reactions can be treated with topical corticosteroids, ocular involvement requires ophthalmologic evaluation.

Scorpiones

The order Scorpiones (scorpions) comprises terrestrial arachnids most commonly encountered in tropical or arid

regions, including the southwestern United States, northern Africa, Mexico, and the Middle East. These nocturnal creatures seek shelter under stones and bark during the day. As with other arachnids, scorpions are generally shy and sting humans only when provoked. Although capable of producing significant local wounds, the potential for serious, even lethal, cardiovascular complications following a scorpion sting remains of primary concern.[1] The scorpion of principal interest in the United States is *Centruroides exilicauda* (formerly *C. sculpturatus*), whose sting is potentially fatal (Fig. 210-5). *Centruroides* species possess a small spine at the base of the stinger, a feature which may help distinguish them from other species of scorpion.[28,29]

CLINICAL FINDINGS Scorpion stings usually produce an immediate, sharp, burning pain. This may be followed by numbness extending beyond the sting site. Regional lymph node swelling, and, less commonly, ecchymosis and lymphangitis, may develop. *C. exilicauda* venom contains a powerful neurotoxin, capable of producing muscle spasticity, nystagmus, blurred vision, slurred speech, excessive salivation, respiratory distress, pulmonary edema, and myocarditis.[30–35] Infants and young children are at the greatest risk for serious complications.[29]

MANAGEMENT Mild scorpion envenomations may only require symptomatic treatment, including analgesics and local ice compresses. Any child stung by a scorpion, especially if identified as *C. exilicauda*, should be hospitalized for close monitoring of respiratory, cardiac, and neurologic status.[36] Specific antivenin is the treatment of choice for severe envenomation. Studies indicate that *C. exilicauda* antivenin is safe, with a low incidence of anaphylactic reaction following infusion and a rapid onset of symptom relief.[34,37] Although serum sickness is common after antivenin infusion, it is usually self-limited and can be managed with antihistamines and corticosteroids.[34,37]

◀ **FIGURE 210-5** *Centruroides* scorpion.

Acarina

The order Acarina contains ticks and mites (see Fig. 210-1). Ticks are the most numerous members of this order, with approximately 800 known species. They are important worldwide as vectors of systemic disease, capable of transmitting viruses, rickettsia, spirochetes, bacteria, and parasites to humans.

MITES (See Chap. 208)

TICKS Ticks are divided into two families: Ixodidae (hard ticks) and Argasidae (soft ticks). Hard ticks are responsible for the majority of tick-related disease. Ticks pass through multiple stages during their life cycle, including egg, larva, nymph, and adult, and require blood meals for transition between the latter three stages. Ticks are distinguished from other mites by the presence of a barbed hypostome, which is inserted into the skin for feeding (Fig. 210-6). Ticks ingest blood from a diversity of vertebrate hosts including birds, reptiles, and mammals.[38] Adult hard ticks are capable of ingesting several hundred times their unfed body weight when taking a blood meal and may survive for months without feeding. When searching for a suitable host, hard ticks exhibit a unique behavior called "questing" during which the tick crawls to the edge of a leaf or blade of grass and holds its front pair of legs stretched out in order to grab onto a passing host.[39–41] Humans often become infested by contact with tall grass or brush that harbors the unfed ticks or by their association with domestic animals like cats or dogs. Ticks are attracted to the smell of sweat, the color white, and body heat. Once on a host, a tick may spend up to 24

▲ **FIGURE 210-6** *Dermatocentor variabilis* feeding. The tick has been attached for 24 hours.

hours in search of a protected site to feed, such as a skin fold or the hairline. Tick feeding time ranges from 2 hours to 7 days, with the tick dropping off of the host once fully engorged.

Many different tick species are responsible for local tick bite reactions and transmission of disease in human hosts. In the United States, *Ixodes scapularis* (deer tick or black-legged tick), *Dermacentor andersoni* (American wood tick), *D. variabilis* (American dog tick), *I. pacificus* (Western black-legged tick), and *Amblyomma americanum* (Lone Star tick) are among the most common. In the Eastern Hemisphere, important tick species include *I. ricinus* (castor bean tick or sheep tick) and *I. persulcatus* (Taiga tick). Among the diseases transmitted by ticks are Lyme disease (see Chap. 187), ehrlichiosis, babesiosis, Rocky Mountain spotted fever (see Chap. 199), Colorado tick fever, Q fever, and tularemia (see Chap. 180).

Clinical Findings. The majority of tick bites occur in the spring and summer, coinciding with the life cycle of the tick. Tick bites are usually painless, as the tick introduces an anesthetic and anticoagulant substance when biting. Often, a person will not even know he or she has been bitten but will see or feel an attached tick while scratching or bathing. Tick bites may incite foreign body granuloma formation, reactions to injected toxins and salivary secretions, and hypersensitivity responses. Rarely, delayed hypersensitivity reactions occur with fever, pruritus, and urticaria.[42] A red papule is usually seen at the bite site, and may progress to localized swelling and erythema.[42] A cellular response to the bite can lead to induration and nodularity after a few days. Foreign-body reactions may occur when mouth parts are retained in skin after incomplete removal of the tick. Chronic tick bite granulomas may present diagnostic problems and persist for months to years.

Tick paralysis is a potentially lethal complication of tick infestation and is thought to be caused by a neurotoxin contained within tick salivary secretions. The illness may start with headache and malaise and rapidly progress to an acute ascending lower motor neuron paralysis, similar to that of Guillain-Barré syndrome, which may result in respiratory failure and death.[43,44] Several species of tick are capable of causing tick paralysis, including *D. andersoni, D. variabilis,* and *A. americanum*. Typically, the onset of symptoms occurs 4 to 6 days after attachment of the tick. Symptoms resolve once the tick is removed from the patient. Supportive measures, including mechanical ventilation, may be required until symptoms resolve.

Management. After potential exposure, the skin should be inspected for ticks to remove them before they begin feeding and risk transmitting disease. Once a tick has inserted its hypostome into the skin, it must be forcibly removed. Although many methods have been suggested for removing ticks, physical methods, such as slow, steady pulling on the tick, are probably the safest and most useful. Retained tick parts should be removed surgically if necessary to prevent development of foreign body granulomas. Antibiotic prophylaxis after tick bites is controversial. Although there is some evidence that prophylaxis may help prevent acquisition of Lyme disease and other vector-borne illnesses, the risks of antibiotic therapy must be weighed against the risks and prevalence of vector-borne illnesses in a particular region. In areas highly endemic for Lyme disease, the benefits of prophylactic treatment may outweigh the risks, especially in cases in which the tick has been attached to the host for an extended period of time and can accurately be identified as a vector for Lyme borreliosis. In these cases, the authors suggest a course of oral doxycycline (see Chap. 187).

CHILOPODA AND DIPLOPODA

The arthropod classes Chilopoda and Dipoploda are composed of centipedes and millipedes, respectively. Centipedes and millipedes are terrestrial arthropods with multiple body segments.

Centipedes

Centipedes, which have one pair of legs per body segment, are nocturnal carnivores that may produce extremely painful bites with a pair of poisonous claws. The *Scolopendra* species is found throughout the southwestern U.S. and may attack when its habitat is disturbed. In addition to severe pain and erythema following a bite, localized sweating, edema, secondary infection, and ulceration may be seen. There are also case reports of proteinuria, acute coronary ischemia, and myocardial infarction following centipede bite.[45–49] Treatment consists of analgesia, including injection of local anesthetics, antihistamines, and tetanus prophylaxis. Antibiotics may be required to treat secondary infection.

Millipedes

Millipedes, which have two pairs of legs per body segment, usually feed on living and dead plant matter. They lack poison claws and neither bite nor sting. However, millipedes possess repugnatorial glands on either side of each segment and may emit a toxic substance if threatened. The oily, viscous liquid can cause a brownish discoloration of the skin that can persist for months and may produce burning and blistering.[50–52] Severe reactions are mainly seen in tropical species. Some species are capable of squirting the toxin several inches. This can result in various eye lesions including periorbital edema, periorbital discoloration, conjunctivitis, and keratitis.[53] Although ophthalmologic evaluation should be considered for eye exposures, thorough immediate cleansing with soap and water is usually adequate for skin contact.

INSECTA

The class Insecta contains several orders of medical importance: Anoplura (lice; see Chap. 208), Diptera (flies, mosquitoes), Coleoptera (beetles), Hemiptera (bedbugs, kissing bugs), Siphonaptera (fleas), Hymenoptera (ants, bees, wasps), and Lepidoptera (butterflies and moths). Insects can be distinguished from other arthropods by the presence of three body segments, a pair of compound eyes, paired antennae, and six legs.

Diptera

The order Diptera, or true flies, contains several important families: Culicidae (mosquitoes), Simuliidae (black flies), Ceratopogonidae (biting midges), Tabanidae (horse flies and deer flies), Psychodidae subfamily Phlebotominae (sandflies), and Glossinidae (tsetse flies). Not only do members of this order inflict cutaneous injury with their bites, they are also, collectively, responsible for the transmission of more disease worldwide than any other arthropod order.

The family Culicidae contains more than 2000 species of mosquito, many of which transmit disease. Several genera of mosquito, including *Anopheles*,

Culex, and *Aedes*, serve as vectors for malaria, yellow fever, dengue fever, filariasis, and encephalitis viruses, including West Nile virus, which caused the largest arboviral meningoencephalitis outbreak ever recorded in North America.[54] Because male mosquitoes lack piercing mouthparts, female mosquitoes inflict all human bites. Mosquito bites incite the formation of pruritic wheals and papular lesions, which form in response to irritating salivary secretions that are injected by the mosquito to prevent coagulation. Mosquito bites may have an urticarial, vesicular, eczematous, or granulomatous appearance. Bite reactions usually subside over several days.

Other biting flies include midges, black flies, horseflies, tsetse flies, and sandflies. Black flies of the family Simulidae are vectors for onchocerciasis (African river blindness, see Chap. 207) and tularemia (see Chap. 180). Within the Tabanidae family, *Tabanus* species (horse flies) also serve as vectors for tularemia, and *Chrysops* species (deer flies or mango flies) are responsible for transmission of *Loa loa* filariasis (see Chap. 207) and tularemia. Cutaneous myiasis (Fig. 210-7) may be caused by the deposition of fly larvae into intact skin or open wounds by several species, including *Dermatobia hominis* (human botfly).[55,56] Numerous species of sandflies also spread disease with *Phlebotomus* species transmitting Old World leishmaniasis (see Chap. 206) and *Lutzomyia* species transmitting New World leishmaniasis and Carrión disease (bartonellosis; see Chap. 206). *Glossina* species (tsetse flies) serve as vectors for African trypanosomiasis (see Chap. 206).

Diptera bites should be cleansed thoroughly with soap and water to avoid secondary infection. A short course of topical steroids and systemic antihistamines may be used to control pruritus. Rare allergic reactions should be treated aggressively. Cutaneous myiasis is often best treated with local surgical excision of the larva and involved surrounding tissue. The antihistamines cetirizine or ebastine taken prophylactically as a single 10-mg dose have been demonstrated in studies to decrease wheal formation and subsequent pruritus following mosquito bites.[57,58]

▲ **FIGURE 210-7** Cutaneous myiasis: A domed nodule resembling a furuncle at the site of deposition of a botfly larva. The lesion has a central pore through which the posterior end of the larva intermittently protrudes. The inset shows the larva that has been extracted.

Coleoptera

The Coleoptera order is the largest order in the animal kingdom, containing over 300,000 species of beetles. Although beetles generally do not bite or sting humans, many species of beetle contain chemicals that can cause blistering of human skin.[59] Although some beetles are capable of emitting these chemicals, most cases of blister beetle dermatosis are the result of a beetle being crushed against the skin. The most well-known beetle to cause blister beetle dermatosis is *Lytta vesicatoria*, the Spanish fly, which is found in southern Europe and contains the chemical cantharidin. Cantharidin, which causes vesiculation of the skin, is used in the treatment of warts and molluscum contagiosum. Several other species of beetle found in different regions of the world, including the central and southeastern United States, contain similar chemicals and can cause blistering.[60,61] *Paederus* species (rove beetles) contain the vesicant pederin and are another cause of beetle dermatitis.[61] Washing of affected areas immediately after exposure may help prevent vesiculation. Blisters should be treated with local wound care until resolved.

Another beetle with dermatologic significance is the carpet beetle. The most common species found in the United States are *Attagenus megatoma* (black carpet beetle) and *Anthrenus scrophulariae* (common carpet beetle). Although adult carpet beetles are of little clinical importance, cutaneous exposure to carpet beetle larvae, which feed on wool, carpets, clothing, and other organic material, can cause an allergic papulovesicular dermatitis.[62]

Hemiptera

The Hemiptera order encompasses two families of clinical significance: the Cimicidae, which includes *Cimex lectularius* (bedbugs), and the Reduviidae, which includes *Triatoma* species (kissing bugs). Although most members of this order are herbivores, these two families are frequent human parasites.

CIMICIDAE The common bedbug (*C. lectularius*; see Fig. 210-1) has been a scourge of mankind for centuries. The bedbug is a nocturnal feeder that stays hidden during the day in cracks and crevices of headboards, in picture frames, behind loose wallpaper, or any other dark place that accommodates its flattened body.[1] After a potential victim has gone to bed, the insects come out of hiding for a blood meal. They are attracted to the warmth and carbon dioxide production of their victim. Bedbugs usually complete their meal in a matter of minutes and then return to hiding. Although bedbugs can survive for 1 year or more without feeding, they usually seek a blood meal every 5 to 10 days.[1] Bedbugs are common and are distributed worldwide. They can be spread in clothing and baggage of travelers and visitors, on secondhand mattresses, and via laundry.

Along with other blood-sucking arthropods, the role of bedbugs in infectious dis-

▲ **FIGURE 210-8** Papular urticaria: Bedbug bites. These are pruritic urticarial papules, arranged in a row (breakfast, lunch, and dinner).

ease transmission has gained increasing interest in recent years. Although laboratory studies have shown that these insects are capable of incubating and shedding pathogens such as hepatitis B virus for several weeks after feeding on an infected bloodmeal, there is currently no convincing evidence that *Cimex* species act as vectors in their natural state.[63]

Bedbug bites are usually painless and may be overlooked unless large numbers of bites are present. Bites are usually multiple and may be grouped in a linear fashion. A row of three bedbug bites is sometimes referred to as *breakfast, lunch, and dinner*[64] (Fig. 210-8). Reactions to the bites consist of wheals and papules, often with a small hemorrhagic punctum at the center. Bullous reactions to bites are also possible in sensitized individuals, and hypersensitivity reactions have been reported.[64–66] Flecks of blood may also be found on bed linens. Minimal symptomatic treatment of bites and good local wound care to prevent pruritus and secondary infection are sufficient in most cases.[66] In the presence of a secondary infection, topical antiseptic lotion or antibiotic cream should be applied.[65] Topical corticosteroids may be used for pruritus. Once a bedbug infestation has been diagnosed, a professional exterminator is often necessary to eradicate the insects.

REDUVIIDAE The kissing bug, or assassin bug, belongs to the family Reduviidae and is distinguished by a triangular shape on its back formed by the meeting of the membranous wings. All reduviid bugs possess piercing mouthparts used to feed on blood. Most species of Reduviidae are found in the Americas, with a few species located in Africa, Asia, and Europe. Within the United States, these insects are found in the Southwest from Texas to California. Reduviidae are of great clinical significance because they act as vectors for *Trypanosoma cruzi*, the causative agent of Chagas disease, which affects an estimated 15 million to 20 million people living in South and Central America (see Chap. 206). Kissing bugs earned their name for their predilection to bite on or near the lips. After taking a blood meal, reduviids characteristically turn around and defecate immediately. The trypanosomes are inoculated when the victim subsequently scratches the infected feces into the wound.[1]

Reduviid bugs are found in the southwest United States, especially from Texas to California.[67] Although they are nocturnal feeders and usually prey on rodents, during periodic flights, they move toward the lights of desert homes. Although defensive bites of reduviids are extremely painful, the painless bite of a feeding reduviid occurs only while the host is sleeping, because the blood meal takes several minutes to complete. Bites have been associated with papular, urticarial, and bullous reactions. A small proportion of victims may develop generalized, acute allergic reactions that cause the victim to awaken with sudden onset anaphylactic signs and symptoms.[68] Defensive bites may incite more severe local cutaneous reactions, including necrosis and ulceration.

Siphonaptera

Fleas belong to the insect order Siphonaptera (see Fig. 210-1). These small bloodsucking insects are wingless and are capable of jumping to a height of 18 centimeters. Members of the family Pulicidae, most notably the rat fleas (*Xenopsylla cheopis* and *X. brasiliensis*), transmit bubonic plague (*Yersinia pestis*) (see Chap. 180). Other members of this family are also capable of transmitting disease, including the cat flea (*Ctenocephalides felis*), which is a vector for bubonic plaque and endemic typhus (*Rickettsia prowazekii*).

Flea bites produce minimal irritation in nonsensitized individuals, typically resulting in linear or clustered urticarial papules, frequently found on the lower legs (Fig. 210-9). In sensitized individuals, most often young children, the antigenic saliva is capable of producing papular urticaria, an eruption characterized by recurrent or chronic pruritic papules occurring on exposed skin areas.[1,69] Bullous reactions to flea bites may also develop in patients with hypersensitivity (see eFig. 210-9.1 in on-line edition.) Conservative topical therapy with corticosteroids and antipruritics, along with oral antihistamines, is usually sufficient for most flea bites. Antibiotics may be necessary should secondary bacterial infection develop. Once a flea infestation occurs, complete eradication of the insects is necessary to prevent additional bites.

The Tungidae family contains a tropical flea species called *Tunga penetrans* (the sand flea, chigoe flea, or jigger) that is the etiologic agent of tungiasis, an infestation caused by penetration of the adult female flea into human skin to lay

▲ **FIGURE 210-9** Papular urticaria: Flea bites. Multiple, pruritic urticarial papules, usually < 1 cm in diameter; they may be topped by a vesicle. Here they occur on the legs of a child.

▲ **FIGURE 210-10** Tungiasis: A necrotic periungual papule on the fifth toe. The larva can be visualized by removing the overlying crust.

eggs.[70,71] Lesions occur almost exclusively on the feet (Fig. 210-10), usually on the plantar surface or in the web spaces. Tungiasis may lead to pain, pruritus, secondary bacterial infection, and, sometimes, autoamputation of toes.[72] Death from tetanus has also been reported. Treatment options include surgical excision of the affected area or killing the adult female flea with cryotherapy or topical agents. Tetanus prophylaxis is recommended, and systemic antibiotics should be used when necessary.

Hymenoptera

The order Hymenoptera contains the families Apidae and Bombidae (bees), Vespidae (wasps), and Formicidae (ants). Many members of this order have evolved poison glands used for defense and/or hunting. Aside from local cutaneous reactions, Hymenoptera stings are an important problem because of their high incidence and ability to produce fatal anaphylactic reactions.[73]

All Hymenoptera stings are inflicted by female insects via a modified ovipositor or egg-laying apparatus. Most Hymenoptera stings occur when the nest or individual insects are threatened. The honeybee stings with a barbed ovipositor, which it leaves impaled into the skin. The honeybee dies after stinging because it eviscerates itself to expel its paired venom sacs. The stinger should be removed as swiftly as possible after a sting because the musculature attached to the stinger can continue to pump venom into the skin. If possible, the stinger should not be squeezed during removal with fingers or tweezers as additional venom can be injected into the victim. One method for removal is to scrape the edge of a credit card or the dull blade of a butter knife along the skin at an angle almost parallel to the surface. This will dislodge the stinger while minimizing the injection of additional venom. Other Hymenoptera species lack a barbed stinger and may sting repeatedly.

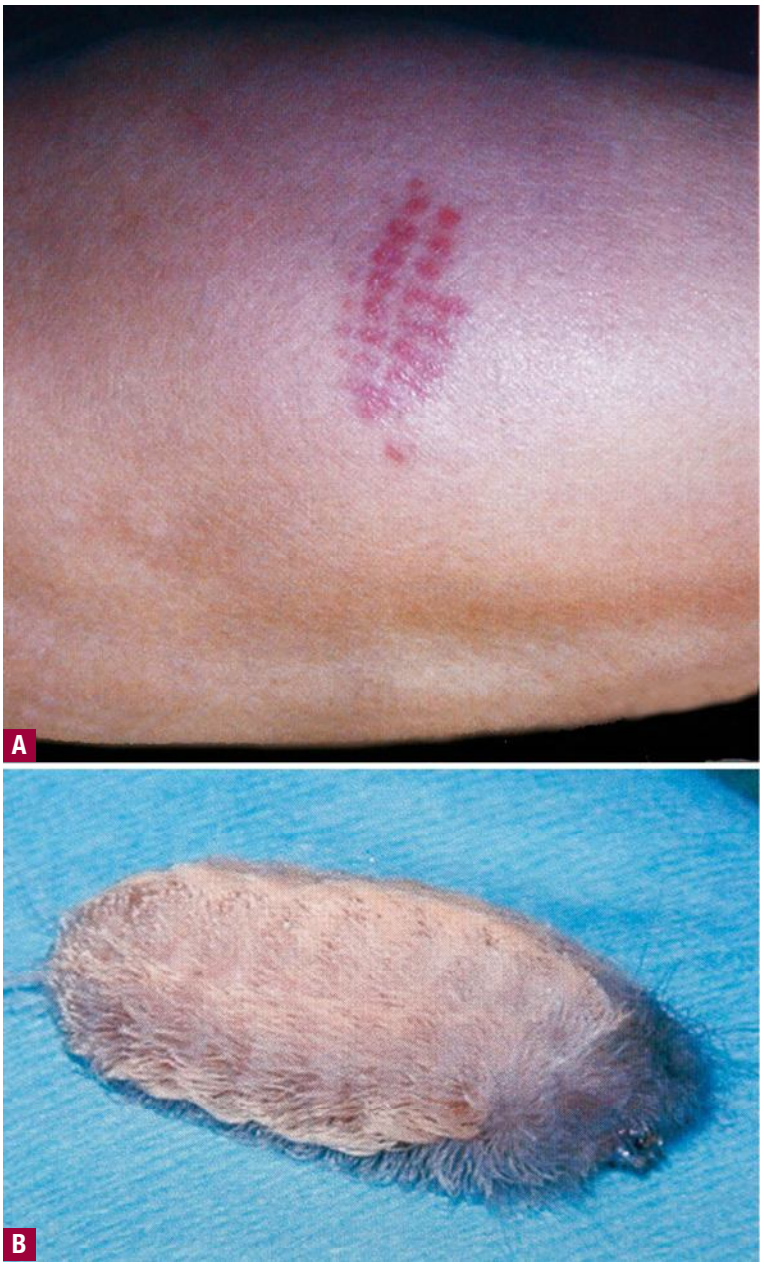
Imported fire ants (*Solenopsis invicta*), originally from Brazil, are an aggressive species that has become well established in the southeastern United States. *Solenopsis* venom contains a nonproteinaceous, hemolytic factor identified as a dialkylpiperidine, solenopsin D, which induces mast cell degranulation.[74] Imported fire ants often attack in groups. Their sting results in an intense inflammatory, wheal-and-flare reaction that becomes a sterile pustule and may progress to localized necrosis and scarring. Sensitized individuals may experience significant bullous reactions following a sting. When attacking, the ants tend to bite the flesh with their powerful jaws and then pivot and sting in a circular pattern, resulting in ring-shaped lesions.

CLINICAL MANIFESTATIONS Hymenoptera stings typically produce immediate burning and pain, followed by the development of an intense, local, erythematous reaction with swelling and urticaria. This "typical" reaction to hymenoptera stings usually subsides within several hours. However, more severe local reactions can occur, including extensive swelling at the sting site and prolonged induration lasting for up to 1 week. A cell-mediated immune response has also been implicated in these reactions.[75] Generalized systemic reactions to hymenoptera stings occur in approximately 0.4 percent to 3.0 percent of patients. Anaphylactic reactions may be evident as generalized urticaria, angioedema, and bronchospasm.

MANAGEMENT Treatment of a Hymenoptera sting is governed by the severity of the reaction. Mild local cutaneous reactions may only require local cleansing, application of ice, and possible injection of local anesthetic to control pain. Oral or parenteral diphenhydramine may help control urticaria and pruritus. Anaphylaxis must be treated vigorously with subcutaneous epinephrine (0.5 mL of 1:1000 dilution) and the institution of supportive measures. Individuals with known Hymenoptera hypersensitivity should always carry a preloaded epinephrine-filled syringe for emergency self-administration. Desensitization therapy should be considered for any patient with a positive intradermal skin test to Hymenoptera venom and a history of sting-induced anaphylaxis.

Lepidoptera

The Lepidoptera order is the second largest order of insects and contains over 100,000 species of caterpillars, moths, and butterflies. An estimated 100 to 150 species within this order are thought to produce *lepidopterism*, the term used to describe the aggregate of medical effects caused by caterpillars, moths, and butterflies.[76,77] Multiple theories regarding the mechanisms of lepidopterism have been proposed, including mechanical irritation by pointed hairs (setae), toxin injection through hollow setae, and cell-mediated hypersensitivity to the hairs. One well-known cause of erucism or caterpillar dermatitis is *Lymantria dispar* (gypsy moth caterpillar).[78,79] Cutaneous contact with hairs from this caterpillar may produce a pruritic dermatitis characterized by multiple erythematous papules often arranged in linear streaks. Windborne hairs may produce keratoconjunctivitis and respiratory symptoms. *Megalopyge opercularis* (asp or puss caterpillar), which can inject venom through its hollow syringe-like hairs, is capable of inflicting an intensely painful sting, and may produce a characteristic train-track pattern of purpura at the sting site (Fig. 210-11).[80,81] Other species that cause lepidopterism in the Americas include *Automeris io* (io moth), *Euproctis chrysorrhoea* (brown-tailed moth), *Sibine stimulate* (saddleback moth), and *Hemerocampa pseudotsugata* (Douglas-fir tussock moth).



▲ **FIGURE 210-11** **A.** Cutaneous reaction from contact with a puss caterpillar showing the typical grid-like pattern. **B.** Pus caterpillar (*Megalopyge opercularis*) demonstrating the corresponding grid-like pattern of its hairs.

Treatment for lepidopterism is largely symptomatic. Systemic antihistamines, topical preparations containing menthol and camphor, and moderate to high potency topical corticosteroids can be used to control pruritus. Systemic steroids may be beneficial for severe reactions. The intractable pain caused by the sting of the puss caterpillar may require oral or parenteral narcotic analgesics. Embedded setae can be removed from the skin by "stripping" with adhesive tape.

PREVENTION

Several relatively simple steps can be taken to minimize the occurrence of arthropod bites. Spider bites can be reduced by wearing gloves while working in crawl spaces, garages, or basements or when manipulating woodpiles or rubbish piles. In scorpion endemic areas, shaking out clothing and footwear before putting it on is advisable. Wearing appropriate clothing with good coverage and avoiding rubbing against high brush and grass may help avoid tick bites. Bright colors and artificial scents like perfume, which are attractants for mosquitoes and other flying insects, are best avoided on warm summer nights. In tropical regions, proper footwear is essential to preventing tungiasis. Infestations of living areas by arthropods, including fleas and bedbugs, are difficult to eliminate and may require the assistance of a professional exterminator.

Chemical repellents are also useful in preventing arthropod bites. Several different chemical repellents have been studied, including *N,N*-diethyl-3-methylbenzamide (DEET, previously diethyltoluamide), picaridin (KBR 3203), and *p*-menthane-3,8-diol (Eucalyptus oil). The most effective repellent for all biting flies, including mosquitoes, is DEET, which is available in many products in concentrations up to 100 percent. Generally, a product containing 10 percent to 30 percent DEET provides adequate protection for most outdoor activities, with higher concentrations of DEET providing longer protection times. Although DEET has an excellent safety record, there are reports of encephalopathy developing, particularly in children, after exposure to this chemical.[82,83] For this reason, only products with DEET concentrations of less than 10 percent should be used on children. Permethrin, an insecticide often used to treat pediculosis and scabies, is available as a tick repellent that can be sprayed on clothing and fabrics, including tents and sleeping bags, and remains effective through several wash cycles. Combined use of permethrin-treated clothing and DEET applied to the skin provides the maximum protection.

SECTION 34

OCCUPATIONAL SKIN DISEASES

CHAPTER 211

Occupational Skin Diseases Due to Irritants and Allergens

James S. Taylor
Apra Sood
Antoine Amado

Occupational dermatoses are any abnormal conditions of the skin caused or aggravated by substances or processes associated with the work environment. Occupational skin diseases (OSDs) are a major public health problem, because they are common, are often chronic, and have significant economic impact on society and on workers.[1] A thorough knowledge of potential irritants, allergens, and other causative factors in the workplace, as well as the workers' compensation system, is essential for the dermatologist dealing with occupational dermatoses.

HISTORICAL ASPECTS AND RESOURCES

EPIDEMIOLOGY

The U.S. Department of Labor publishes annual incidence statistics on the safety and health of employees in private industry (http://www.osha.gov). In 2003, of the 4.4 million nonfatal job-related injuries and illnesses reported, 6.2 percent (269,500 cases) were work-related illnesses. Of these, skin disorders were the second most common reported illness, accounting for 43,400 cases.[2] Occupational contact dermatitis is the most commonly reported OSD, and in most countries, the reported incidence of occupational contact dermatitis varies from 5 to 19 cases per 10,000 full-time workers per year.[3] Incidence rates also vary based on the specialty of the reporting physicians; rates are six to eight times higher in some studies when cases are reported by occupational physicians rather than by dermatologists.[4]

The number of OSD cases has declined, especially in the past 4 years, possibly due to better prevention, the ease with which workers' compensation cases are accepted, and a change in reporting patterns of employees or employers.[5] However, a large number of minor or transient cases still go unreported or untreated, so the exact incidence is not known.

IRRITANT CONTACT DERMATITIS (See Chap. 46)

Irritant contact dermatitis (ICD) is a nonimmunologic inflammatory reaction of the skin to contact with a chemical, physical, or biologic agent. ICD is the most common OSD, accounting for up to 80 percent of cases, although some authors have found a relatively equal distribution of ICD and allergic contact dermatitis (ACD).[3] In addition to the more common acute and chronic eczematous reactions, the clinical spectrum of ICD includes ulceration, folliculitis, acneiform eruptions, miliaria, pigmentary alterations, alopecia, contact urticaria, and granulomatous reactions (Table 211-1).[6]

◀ Irritant contact dermatitis of hand: Subacute/chronic. Erythema, edema, scaling, fissuring, crusting of the palmar aspect of the hand and wrist; the other hand had similar involvement. The patient, a housewife, is atopic and has ignored instructions to wear gloves during work in the kitchen and to use lubricating creams.

OCCUPATIONAL SKIN DISEASES DUE TO IRRITANTS AND ALLERGENS AT A GLANCE

- Skin disorders are the second most commonly reported occupational disease, accounting for approximately 10 percent of occupational disorders.
- Irritant and allergic contact dermatitis comprise a significant number of cases of occupational skin disease. The majority involve workers in the manufacturing and service industries.
- Chronic cumulative irritant contact dermatitis is the most common form of occupational irritant contact dermatitis.
- Approximately 80 percent of individuals with occupational contact dermatitis have hand involvement.
- Patch testing should be performed to rule out an allergic contact dermatitis in all cases in which an initial chronic irritant dermatitis is suspected.

Major Categories of Irritant Contact Dermatitis

The two major types of occupational ICD are acute ICD and cumulative ICD.

TABLE 211-1
Clinical Features of Irritant Dermatitis and Suggested Etiology

- Eczema (acute and cumulative irritant exposure)
  - Industrial cleaners
  - Water, soaps, and detergents
  - Weak acids and alkalies
  - Oils and organic solvents
  - Oxidizing agents (H_2O_2, benzoyl peroxide)
- Ulcerations and burns
  - Strong acids, especially chromic, hydrofluoric, nitric, hydrochloric, sulfuric
  - Strong alkalis, especially calcium oxide, sodium hydroxide, potassium hydroxide, ammonium hydroxide, calcium hydroxide, sodium metasilicate, sodium silicate, potassium cyanide, trisodium phosphate
  - Salts, especially arsenic trioxide, dichromates
  - Solvents, especially acrylonitrile, carbon bisulfide
  - Gases, especially ethylene oxide, acrylonitrile
- Folliculitis and acneiform eruptions
  - Arsenic trioxide
  - Glass fibers
  - Oils and greases
  - Tar
  - Asphalt
  - Chlorinated naphthalenes
  - Polyhalogenated biphenyls
- Miliaria
  - Occlusive clothing
  - Adhesive tape
  - Ultraviolet and infra-red radiation
  - Aluminum chloride
- Pigmentary changes
  - Hyperpigmentation
    - Any irritant or allergen, especially phototoxic agents such as psoralens, tar, asphalt, phototoxic plants, others
    - Metals,[a] such as inorganic arsenic (systemically), silver, gold, bismuth, mercury
    - Radiation: ultraviolet, infra-red, microwave, ionizing
  - Hypopigmentation[b]
    - p-tert-Amylphenol and butylphenol
    - Hydroquinone
    - Monobenzyl and monomethyl ether of hydroquinone
    - p-tert-Catechol
    - p-Cresol
    - 3-Hydroxyanisole
    - Butylated hydroxyanisole
    - 1-tert-Butyl-3,4-catechol
    - 1-Isopropyl-3,4-catechol
    - 4-Hydroxypropriophenone
- Alopecia
  - Borax
  - Chloroprene dimers
- Urticaria
  - Numerous chemicals, cosmetics, animal products, foods, plants, textiles, woods
- Granulomas[b]
  - Keratin
  - Silica
  - Beryllium
  - Talc
  - Cotton fibers
  - Bacteria
  - Fungi
  - Parasites and parasite parts

[a]Some metals are allergens.
[b]Some agents listed are allergens.
From Lammintausta K, Maibach HI: Contact dermatitis due to irritation, in *Occupational Skin Disease*, 2nd ed, edited by Adams RM. Philadelphia, WB Saunders, 1990, p 11.

These and other sub-types are discussed in Chap. 46.

ACUTE IRRITANT CONTACT DERMATITIS, INCLUDING CHEMICAL BURNS Acute eczematous dermatitis after exposure to a potent irritant, often an acid or alkali, may overlap with chemical burns. Highly irritating chemicals may induce a reaction in anyone if the concentration and duration of action are sufficient. The intrinsic nature of the chemical is also important. Common irritants in the workplace are discussed in Common Occupational Irritants later in the chapter. In national statistics for work-related injuries, acute ICD reactions are often classified as chemical burns (Fig. 211-1).

CUMULATIVE IRRITANT CONTACT DERMATITIS Cumulative ICD, the most common type of ICD, develops slowly after multiple subthreshold exposures to mild irritants (soap, water, detergents, industrial cleansers, solvents, etc.) under a variety of conditions.[7] Some of the high-risk occupations for ICD are listed in Table 211-2.

The other categories of ICD, as well as predisposing factors, including exogenous as well as endogenous factors, are discussed in Chap. 46. Atopic individuals have an increased susceptibility to skin irritation and account for a large percentage of workers' compensation dermatitis claims.

LOW-HUMIDITY DERMATITIS Workers, especially atopic individuals who are subjected to low relative humidity at work (Table 211-3),[8] are also at risk for developing dermatitis, especially with the presence of other irritants. When relative humidity is below 35 percent to 40 percent, the stratum corneum becomes drier and more brittle, and shows increasing permeability to marginal irritants. Symptoms such as pruritus and burning may be the only complaints and are more distressing than physical signs, which may involve exposed or covered areas. Differential diagnosis includes irritation from airborne substances, other dermatoses, and psychogenic causes.

▲ **FIGURE 211-1** Acute irritant contact dermatitis on the hand caused by an industrial solvent. There is massive blistering on the palm.

AIRBORNE IRRITANT DERMATITIS Airborne irritants are an important cause of contact dermatitis. The pattern is fairly characteristic, with subjective symptoms of stinging, burning, or smarting sensations. Objective findings range from barely visible diffuse lesions to more severe dermatitis of the eyelids, cheeks, nasal folds, and neck. Some airborne irritant particles cause symptoms only if occluded under clothing in the flexures and other intertriginous body areas.

The most frequent causes are irritating dusts and volatile chemicals, such as solvents, ammonia, formaldehyde, epoxy resins and their hardeners, cement dust, fibrous glass, and sawdust, especially from irritating woods.[9]

Diagnosis of Irritant Dermatitis

The diagnosis of ICD is based on a history of exposure to a known potential irritant, the clinical appearance, and the distribution of lesions.[10] Subacute and

TABLE 211-2
Occupations at Risk for Irritant Contact Dermatitis and Potential Irritants

Occupation	Irritants
Baker	Flour, spices, soaps and detergents, oven cleaners, essential oils, yeast
Beautician	Soaps and detergents, bleaches, solvents
Construction worker	Acids, fibrous glass, concrete, solvents, hand cleaners
Cook	Wet work, soaps and detergents, vegetable and fruit juices, raw meat and fish, spices, sugar and flour, heat
Dental technician	Wet work, adhesives (epoxy and cyanoacrylates), essential oils, orthodontic plasters, amalgam mixtures, solvents
Florist	Wet work, soaps and detergents, fertilizers, herbicides, pesticides, mechanical and chemical plant irritants
Hairdresser	Bleaches, permanent wave solutions, shampoos, soaps and detergents, water
Health care worker	Wet work, soaps and detergents, alcohol, ethylene oxide, medications
Housekeeper	Wet work, soaps and detergents, cleaners, polishes, oven cleaners, disinfectants
Machinist	Solvents, coolants, cutting oils, degreasers, acids, corrosion inhibitors, heat, soaps and detergents, metal filings and swarf
Painter	Paints, solvents, adhesives, paint removers, paintbrush cleaners, soaps and detergents

Adapted from refs. 6, 7, 12, 19, 29, 39.

chronic irritant dermatitis are almost always diagnoses of exclusion. Patch testing (see Chap. 13) is necessary to help distinguish ACD from ICD or to diagnose a superimposed ACD or ICD. More detailed criteria for the clinical diagnosis of ICD are discussed in Chap. 46.

Common Occupational Irritants

SOAPS AND DETERGENTS Soaps and detergents are weak skin irritants; however, excessive use can cause cumulative insult dermatitis in susceptible individuals. The choice of cleanser varies with the job for which it is intended; for example, machinists and auto mechanics need a cleanser with a high detergent and abrasive action. The inappropriate use of products intended as industrial cleansers can also result in dermatitis.

TABLE 211-3
Workers Exposed to Risk of Dermatitis in Low-Relative-Humidity Environments

- Soft contact lens manufacturing workers
- Silicon chip manufacturing workers
- Aircraft crews on long-distance flights
- Office workers
- Resident staff in hospitals and hotels
- Traveling salespersons (from automobile heaters)

Adapted from Uter W, Kanerva L: Physical causes—Heat, cold and other atmospheric factors, in *Handbook of Occupational Dermatology*, edited by Kanerva L et al. Berlin, Springer-Verlag, 2000, p 148; and Leggat PA, Smith DR: Dermatitis and aircrew. *Contact Dermatitis* **54**:1, 2006.

WATERLESS HAND CLEANERS Waterless hand cleaners are formulated to remove tough oil and grease stains and are widely used at work sites where there is no convenient source of water. They should be applied sparingly because they may contain petroleum-derived solvents and may result in dermatitis if overused. Instant hand sanitizers, which often contain high concentrations of alcohol, can be drying to the skin.

ACIDS AND ALKALIS, INCLUDING CHEMICALS THAT CAUSE BURNS Chemical burns are an important cause of occupational injury.[11] Copious irrigation is the primary method of treating all chemical burns; however, certain types of burns require specific antidotes and therapies (Table 211-4).[12]

Inorganic Acids. Inorganic acids are used in large quantities in industry; some of the occupations at risk for exposure are listed in Table 211-5. Acids are common causes of chemical burns and can cause erythema, blistering and necrosis, and discoloration of the skin. Mechanisms of action of common industrial irritants, including acids, are listed in Table 211-6.

TABLE 211-4
Selected Chemical Burns That Require Unique Therapies

Chemical	Treatment
Burning metal fragments of sodium, potassium, and lithium	Extinguish with sand; cover with mineral oil; extract metal particles mechanically.[a]
Hydrofluoric acid	Flush with running water; then administer calcium gluconate: gel (2.5%) followed by intralesional injection, if needed.
Phosphorus	Remove particles mechanically; wash with soap and water; then apply copper (II) sulfate in water for several minutes, remove black copper phosphide, and wash with water.
Phenolic compounds	Perform initial soap and water washing followed by treatment with polyethylene glycol 300 or 400 or ethanol (10%) in water.
Bromine or iodine	Wash frequently with soap and water followed by treatment with 5% sodium thiosulfate.

[a]Use of water to extinguish burning metal fragments is contraindicated because of the formation of highly alkaline hydroxides.
From Bruze M, Fregert S, Gruvberger B: Chemical skin burns, in *Handbook of Occupational Dermatology*, edited by Kanerva L et al. Berlin, Springer-Verlag, 2000, p 325.

OTHER CHEMICALS AND AGENTS

ALLERGIC CONTACT DERMATITIS (See Chap. 13)

ACD is reported less frequently than ICD in the working environment, possibly because most workers are not patch-tested, and thus the disorder is not diagnosed and reported. In a multicenter study conducted by the North American Contact Dermatitis Group that examined 839 cases identified as occupational dermatitis (29 percent of 2889 patients referred for evaluation of contact dermatitis), 54 percent were primarily allergic dermatitis, 32 percent were irritant dermatitis, and 14 percent were conditions other than contact dermatitis that were aggravated by work.[20] In this series, ACD was seen most commonly in nurses; the other occupational groups represented were assemblers, nurse's aides and orderlies, machinists, students, machine operators, auto mechanics, those performing compressing and compacting jobs, and cooks. Aller-

TABLE 211-5
Industries Presenting Risk for Acute Irritant Reactions

Chemical	Industries Presenting Risk
Acids	
Sulfuric	Manufacture of fertilizers, inorganic pigments, textile fibers, explosives, pulp and paper
Hydrochloric	Production of fertilizers, dyes, paints, and soaps
Formic	Textile industry (dyeing and finishing), leather manufacture (delimer and neutralizer), production of natural latex (coagulant)
Acrylic	Manufacture of acrylic plastics (monomer)
Chromic	Chrome plating, copper stripping, and aluminum anodizing operations
Hydrofluoric	Etching and frosting of glass, rust removal, dry cleaning (spot cleaning)
Alkalis	
Calcium, sodium, and potassium hydroxides	Manufacture of bleaches, dyes, vitamins, plastics, pulp and paper, and soaps and detergents
Others	
Arsenic	Smelting of copper, gold, lead, and other metals; semiconductor industry
Beryllium	Aerospace and other industries involved in the production of hard, corrosion-resistant alloys
Cobalt	Manufacture of alloys, ceramics, electronics, magnets, paints and varnishes, or cosmetics; electroplating
Mercury	Industries involved in the manufacture or use of bactericides, dental amalgams, and catalysts
Phosphorus	Manufacture of insecticides and fertilizers

Adapted from refs. 6, 7, 11–19, 29, 39.

gens strongly associated with occupational exposure were rubber (thiuram and carbamate accelerators), epoxy resin, and ethylenediamine. The recent increase in the use of computers has led to an increase in computer-related skin diseases, including ACD caused by plasticizers and possibly neoprene and rubber accelerators in the equipment.[21]

TABLE 211-6
Mechanisms of Action of Common Industrial Irritants

Action	Irritant
Keratin and protein dissolution	Alkalis, soaps
Lipid dissolution	Organic solvents
Dehydration	Inorganic acids
	Anhydrides
	Alkalis (calcium oxide)
Oxidation	Bleaches
Reduction	Salicylic acid
	Formic acid
	Oxalic acid
Keratogenesis	Arsenic
	Tars
	Petroleum

From Birmingham DJ: Dermatoses in occupational diseases, in *Occupational Diseases: A Guide to Their Recognition*, edited by Key MM et al. NIOSH Publication No. 77-181. Washington, DC, US Government Printing Office, 1977.

The principal occupational contact allergens are listed in Table 211-7.

The mechanism of ACD and its clinical manifestations are described in Chap. 13. ACD has now been defined as a three-stage process. The dermatitis is limited to the site(s) of contact with the allergen(s) in stage 1. There is regional dissemination via lymphatic spread in stage 2. In stage 3 there is hematogenous dissemination of ACD at a distance (stage 3A) or systemic reactivation of ACD (stage 3B), also called *systemic contact dermatitis*. Most cases of systemic contact dermatitis are medicament related, but cases related to exposure to mercury or other metals might be occupational in origin. It is important to remember that if a worker develops ACD 2 or 3 days after initial contact with an allergen, the induction of sensitivity must have occurred previously, perhaps during an earlier job.

CONTACT URTICARIA AND IMMEDIATE CONTACT REACTIONS (See Chap. 37)

Contact urticaria syndrome (CUS) comprises a heterogenous group of inflammatory reactions that usually appear within minutes after cutaneous or mucosal contact with the eliciting agent and disappear within 24 hours, usually within a few hours. CUS has four stages: stage 1—localized urticaria, dermatitis, or itching, tingling, or burning; stage 2—generalized urticaria; stage 3—rhinoconjunctivitis, asthma, or gastrointestinal symptoms; and stage 4—anaphylaxis.

There are three varieties of contact urticaria (CU): nonimmunologic CU, immunologic CU, and CU of uncertain mechanism (see also Chap. 37).

Nonimmunologic Contact Urticaria

In nonimmunologic CU, exposed individuals develop reactions without previous sensitization, depending on the nature of the substance, its concentration, the area of skin exposed, and the mode of exposure. Usually the reaction remains localized, and systemic symptoms of wheezing, rhinorrhea, and syncope do not occur. Causative urticants include benzoic acid, sorbic acid, cinnamic acid, cinnamic aldehyde, and nicotinic acid esters.[22,23]

Affected occupational groups and the causative agents to which they may be exposed include the following: gardeners—nettles, various plants, caterpillar hairs, moths, and other insects; cooks—fish, mustard, cayenne pepper, and thyme; and medical and related personnel—alcohol, balsam of Peru, benzocaine, methyl salicylate, tar extracts, tincture of benzoin, witch hazel, and dimethyl sulfoxide.

TABLE 211-7
Major Occupational Contact Allergens

- Acrylics
- Biocides—isothiazolinones, formaldehyde releasers
- Chromate
- Cobalt
- Colophony
- Dyes
- Epoxy resin systems (may need to test with specific resin worker uses)
- Formaldehyde
- Formaldehyde resins
- Fragrances and essences
- Nickel (initial sensitization is usually nonoccupational)
- Plants and woods
- Rubber-processing chemicals

From Rycroft RJG, Frosh PJ: Occupational contact dermatitis, in *Contact Dermatitis*, 4th ed, edited by Frosch PJ, Menne T, Lepoittevin JP. Berlin, Springer-Verlag, 2006, p 717; and English JSC: Allergic contact dermatitis, in *A Colour Handbook of Occupational Dermatology*, edited by English JSC. London, Manson Publishing, 1999.

Immunologic Contact Urticaria (See Chap. 37)

Immunologic CU, an immunoglobulin E–mediated immediate allergic reaction, occurs in persons previously sensitized to a specific agent. Atopic individuals, especially those with atopic dermatitis, are more susceptible. The paradigm is natural rubber latex (NRL) allergy, which results from a reaction to one or more proteins present in NRL.[24] The highest prevalence of NRL allergy is in individuals with spina bifida. Also affected are health care workers; kitchen workers; cleaners; others who wear NRL gloves; and workers involved in the manufacture of rubber bands, surgical gloves, and latex dolls.

The next most common cause of immunologic CU is food items such as raw potato and meat. Other causes are antibiotics and other medications, preservatives, disinfectants, fragrances, epoxy resin hardeners, several woods, birch pollen, and formaldehyde in clothing.

Contact Urticaria of Uncertain Mechanism

CU of uncertain mechanism includes reactions to ammonium persulfate, which is used as a booster in bleaching hair. The dermatitis, which occurs mostly in clients, has a sudden onset and is characterized by erythema, edema, severe itching, urticaria, and occasionally syncope, with wheezing and dyspnea. Hairdressers should be made aware of the seriousness of this problem.

Diagnosis of Contact Urticaria

Other than for NRL allergy, there are few statistical data on CU. Data from Finland indicate that farmers (from exposure to cow dander) account for the most cases but that the highest incidence rate is found among bakers.[23] Diagnosis of immunologic CU typically involves skin testing with the suspected substance and serologic assays for specific immunoglobulin E. When a chemical hapten is the suspected cause, it must be centrifuged with a protein, usually human serum albumin, a non-standard procedure.

CU occurs from direct contact with skin (most cases) or mucosa (e.g., latex and chlorhexidine; the latter may be associated with systemic toxicity), or from contact with airborne allergen (e.g., cinchona, mulberry, xylene). Exposure may be accidental or caused by equipment failure (e.g., xylene). Standard ingredients (e.g., Tinofix) or trace contaminants or impurities (e.g., an anhydride present in sorbitan sesquioleate) may be responsible. CU may be associated with other urticaria such as delayed pressure urticaria.[25] Occasionally, only erythema, burning, and itching occur, but at least some people should develop urticaria at the application site for the reaction to be regarded as CU. Combined CU and delayed allergic eczematous reactions may occur.[25]

DIAGNOSIS OF OCCUPATIONAL SKIN DISEASE

Aspects of Evaluation

Making medical determinations in cases of putative occupational skin disorders and in workers' compensation cases confronts the physician with several challenging tasks: (1) weighing patient assertions and demands concerning the work relatedness of the disease, job changes, and job modifications; (2) serving as social gate keeper with regard to time off from and date of return to work; (3) dealing with lack of adequate workplace information—job description, list of chemicals used at the workplace, and exposures, including material safety data sheets; (4) balancing clinical judgment against technology (e.g., determining whether hand eczema in a machinist is work related when patch test results are negative); (5) establishing causation in the legal sense, which usually requires only probability of work association (within reasonable certainty or more than 50 percent medical certainty), rather than absolute certainty, such as fulfilling Koch's postulates.[26,27]

Thus the essentials in evaluating OSD include the following:

1. Making an accurate diagnosis, including taking a detailed medical and occupational history, performing a complete skin examination, and ordering diagnostic tests as indicated (Table 211-8).
2. Determining causation. Mathias[28] has proposed that a Yes answer to four of the following seven questions is adequate to establish occupational causation and aggravation in contact dermatitis cases and to establish probable cause:
   a. Is the clinical appearance compatible with contact dermatitis?
   b. Are there workplace exposures to potential irritants or allergens?
   c. Is the anatomic distribution of the eruption compatible with job exposure?
   d. Is the temporal relationship between exposure and onset consistent with contact dermatitis?
   e. Have non-occupational exposures been excluded as causes?
   f. Does the dermatitis improve away from work exposure to the suspected irritant or allergen?
   g. Do patch or provocation tests identify a probable cause?
3. Providing recommendations for treatment, prevention, disability status (if any), job placement, rehabilitation, and use of other resources (industrial hygiene consultation and consultations with other medical specialists, such as aller-

TABLE 211-8
Diagnostic Workup for Occupational Irritant Contact Dermatitis and Allergic Contact Dermatitis

History
- Duration, site of onset, progression, symptoms (itching, burning, pain), improvement away from work, treatment to date including response, history of any overt contact allergies
- Occupational history, including current job and process description, changes in current job, previous employment, protective clothing used if any, other workers affected
- Hobbies and part-time jobs
- Medical history, including medical, dermatologic, and surgical history, especially any history of atopic dermatitis, seasonal allergies, and asthma
- Family history of atopy, psoriasis, or other chronic skin conditions

Examination
- Site(s) of eruption
- Morphology of lesions (erythema, eczema, lichenification, pigmentary changes, urticaria, etc.)
- Pattern of involvement

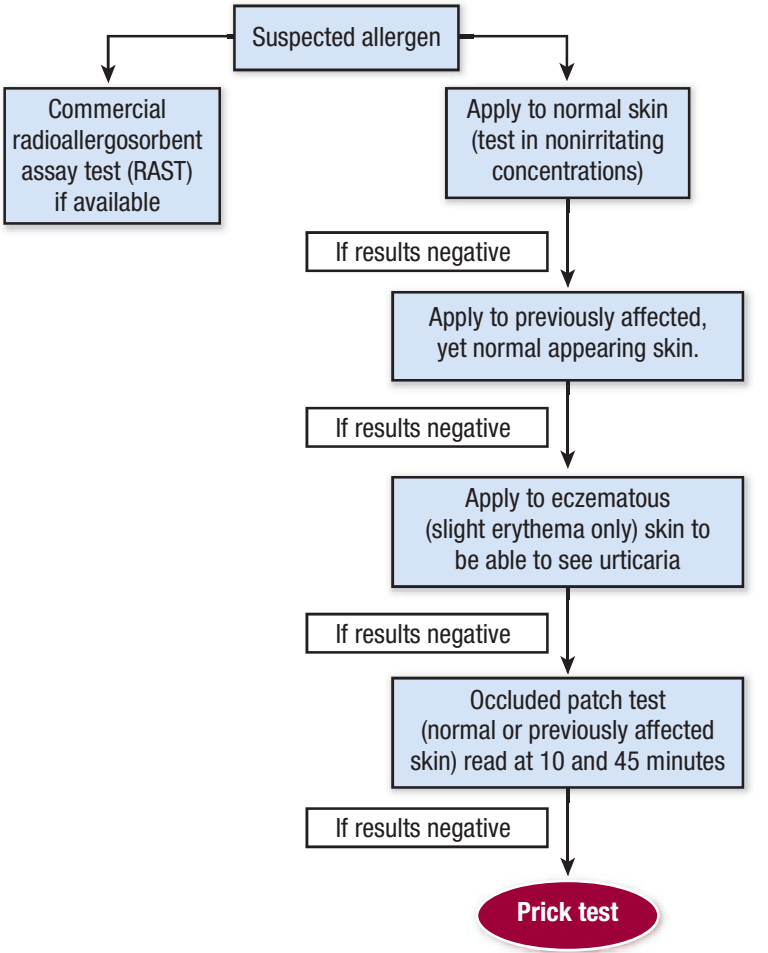
Diagnostic Tests
- Patch testing
- Photopatch testing
- Tests for immediate hypersensitivity (see Fig. 211-2)
  - Radioallergosorbent assay test
  - Open and closed patch tests (read at 10 and 45 min)
  - Prick test
- Repeat open-application "use" test
- Potassium hydroxide examination for fungi, glass fibers
- Fungal, bacterial, and viral smears and cultures
- Skin biopsies
- Dimethylglyoxime test for detecting nickel, other tests (detection of chromates and formaldehyde)

gists, pulmonologists, or occupational medicine physicians).

Diagnostic Testing

PATCH TESTING Because of the importance of ACD in the etiology of OSD, patch testing (see Chap. 13) should be performed in almost all cases of contact dermatitis, even in patients who are thought to have only ICD. Testing should be performed using commercially prepared allergens. Further testing with substances in the worker's environment, including topical medications, protective equipment such as gloves, sensitizing ingredients in cleansers or other products, and occasionally the products themselves (e.g., cutting oils), is sometimes indicated. Testing with irritants such as most solvents, soaps, cement, and the like should not be done, and patch testing with other environmental chemicals should be performed only by knowledgeable individuals to avoid false-positive irritant reactions. Standard texts can be consulted for patch test concentrations.

TESTS FOR IMMEDIATE HYPERSENSITIVITY If type I immediate hypersensitivity is suspected, testing of agents in nonirritating concentrations can be carried out (Fig. 211-2).



▲ **FIGURE 211-2** Testing for immediate hypersensitivity (contact urticaria). (From Taylor JS et al: Contact urticaria, in *Occupational Skin Disease*, 3rd ed, edited by Adams RM. Philadelphia, WB Saunders, 1999, p 111.)

TREATMENT AND PREVENTION

Initial treatment for OSDs depends on the cause and is essentially the same as that for diseases of non-occupational origin. However, it is important that patients be told the specific cause(s) of their disease and methods to avoid recurrences, and be given information on the appropriate use of skin cleansers, topical treatments, and protective clothing as well as on other preventive measures. Most occupational skin disorders are preventable, and their avoidance requires environmental, personal, and medical methods.[29]

Environmental Methods and Workplace Visits

Environmental methods are the preferred control measures, but they are sometimes also the most expensive measures to implement. Environmental methods involve industrial hygiene and environmental engineering interventions such as the following:

1. Hazard identification: Workplace visits are an important but often overlooked part of the evaluation of workers with OSD. Hazard identification and assessment of means of exposure can be evaluated by direct observation and may be required for problem solving, especially when more than one worker is affected.
2. Substitution of less irritating and allergenic chemicals [e.g., rubber gloves without thiurams and carbamates, an alternative resin (phenolic or polyester) for epoxy resins, an alternative metalworking fluid without a sensitizing additive].
3. Isolation and enclosure of the process.
4. Local exhaust ventilation.
5. Chemical dispensers.
6. Good housekeeping.

Personal Methods

BARRIER CREAMS Barrier creams have been called *invisible gloves*, but they are an inadequate substitute for protective clothing and are often used when gloves, sleeves, and face masks cannot be conveniently or safely used. Several types are available: ordinary emollient creams, water-repellant creams, oil- and solvent-resistant creams, and products for use against poison ivy and poison oak. The most effective barrier creams are sunscreens and sunblocks, which ideally should be worn by all outdoor workers. Problems associated with the use of barrier creams are a false sense of security, improper selection and use, allergy to an ingredient (often a preservative or fragrance), potential for increased absorption of occupational chemicals, and inadequate or infrequent application.

SKIN CLEANSERS Skin cleansers were discussed in the section Common Occupational Irritants, earlier in the chapter.

PROTECTIVE CLOTHING Protective clothing ranges from gloves, aprons, hoods, boots, and work shoes to full-body clothing. Fabrics that resist heat, cold, acids, alkalis, solvents, and ultraviolet radiation are available. Certain types are mildew

and fire resistant. Personal protective equipment is addressed by the Occupational Safety and Health Administration in specific standards for general industry, shipyards, marine terminals, and longshoring, including the U.S. Government Code of Federal Regulations (29 CFR Part 1910).[30] Manufacturers of personal protective equipment provide catalogues with guidelines for the selection of clothing for various exposures.

Medical Methods

Physicians often overlook certain medical aspects of prevention. Basic principles include the following:

1. Initial and subsequent employment physical examinations should include appraisals of the skin and evaluation of fitness for work.
2. Workers with skin disease may require accommodation in the workplace.
3. Potentially sensitizing topical preparations (neomycin, bacitracin, benzocaine, etc.) should be avoided when treating OSD.
4. Well-motivated workers should undergo medical and vocational rehabilitation; this is covered by many workers' compensation plans.

Fitness for Work and Workplace Accommodation

The Americans with Disabilities Act of 1990 brought to the fore issues of job placement and accommodation. Most individuals with chronic skin conditions can perform normal work activities, but in some instances accommodation in the workplace is required.[32]

PROGNOSIS AND PERSISTENCE

Although the prognosis of chronic OSD is guarded, there has been improvement, with clearance reported in 70 percent to 84 percent of cases.[33] Minimizing workplace exposure and maximizing patient knowledge regarding potential irritants and allergens is one of the most important factors in improving prognosis.[33,34] Certain conditions, such as chromium sensitivity, have a poor prognosis and are notoriously long lasting. Atopic dermatitis, especially in occupations in which there is heavy contact with water, soaps, and detergents, is also associated with a poor prognosis.

Of the several causes of persistence of OSD, the most important is an incomplete or incorrect diagnosis. Other factors include failure to eliminate the cause(s), improper job placement, improper therapy, the presence of secondary diagnoses (e.g., allergy to topical medications or multiple contact allergies), exposure to cross-reacting substances at home or in vocational activities, and improper cleansing of the skin. Some workers develop an ongoing dermatitis termed *persistent post-occupational dermatitis* for which there is no obvious present cause, precipitated by prior occupational dermatitis. This has significant implications for prognosis and workers' compensation.[35,36]

IMPAIRMENT AND DISABILITY EVALUATION

Evaluation of patients with OSD is discussed in more detail in other sources. However, dermatologists should be aware of the *Guides to the Evaluation of Permanent Impairment*, published by the American Medical Association. The *Guides* chapter on skin disease has been used for more than 30 years to evaluate patients with permanently impairing skin disorders (diseases that have reached maximum medical improvement—often after 6 to 12 months' duration) of both occupational and non-occupational origin. The *Guides* are used by a number of state workers' compensation authorities and provide examples of five classes of impairment ranging from 0 percent to 95 percent.

HEALTH RISK ASSESSMENT

The current scientific approach to risk reduction in occupational health is based on risk assessment, which is separated into four basic elements: hazard identification, dermal exposure assessment, dose-response assessment, and risk characterization.[37,38]

Hazard Identification

Hazard identification involves determining whether exposure to an agent can cause disease or injury using material safety data sheets. Material safety data sheets provide information only about substances considered hazardous; those present in concentrations of less than 1 percent are not required to be listed, and the physician may need to call for additional information.

Dermal Exposure Assessment

Dermal exposure assessment determines the nature and size of populations exposed to a chemical agent via the skin, as well as the magnitude and duration of the exposure. Considerations regarding exposure include the method of exposure: spills, contaminated tools or rags, aerosols or sprays, or permeation of protective clothing. Thus, work activity (e.g., task duration and frequency, amount of chemical used), work substance (molecular weight, particle size, solubility, volatility, etc.), and worker (e.g., surface area exposed, personal hygiene, presence of dermatitis) are three major factors.

Dose-Response Assessment

Dose-response assessment describes the quantitative relationship between the dose at the target and the toxicologic effect. Persons with atopic dermatitis have increased trans-epidermal water loss and enhanced reactivity to irritants.

Risk Characterization

Risk characterization involves the integration of the data to determine safe exposure by comparing exposure levels with levels at which no adverse effects are observed, while allowing for a safe margin of error. With the exception of nickel and chrome exposure, few skin exposures have been characterized in this way, and it may be difficult to do so. Also, attention must be given to percutaneous absorption as well as to dermal exposure.

CHAPTER 212

Occupational Noneczematous Skin Diseases Due to Biologic, Physical, and Chemical Agents

Apra Sood
James S. Taylor

Noneczematous skin diseases caused by biologic, physical, and chemical agents in the workplace are discussed in this chapter. Trauma-related eczema is also included. For epidemiology, incidence, and management of occupational skin diseases, refer to Chap. 211.

SKIN DISEASES DUE TO BIOLOGIC AGENTS

Workers in health care, food services, cleaning and maintenance, and outdoor occupations are at a risk of developing skin infections. Table 212-1 lists some of the occupations associated with increased risk of certain infections.[1]

Establishing a definite relationship between work and a specific infection is not always simple. Laboratory isolation of the infective organism and a supporting medical history and examination are helpful.

Bacterial Infections

STAPHYLOCOCCAL AND STREPTOCOCCAL INFECTIONS (See Chap. 177) Secondary bacterial skin infections due to *Staphylococcus* and *Streptococcus* are common complications of abrasions, lacerations, burns, and puncture wounds. Butchers and meat handlers are likely to develop infected cuts and scratches, paronychia, abscesses, and lymphangitis. Folliculitis and boils are common in farm workers and construction workers. Workers in hot, humid, and dirty environments[2] (see eFig. 212-0.1 in on-line edition) or those working in close contact with infected persons, such as nurses, hairdressers, and manicurists, are at risk. Metalworking fluid contaminated with bacteria is another potential source of infection for workers.[3] The increase in multidrug-resistant bacterial strains and the emergence of community-acquired methicillin-resistance *S. aureus*[4] may present a therapeutic challenge.

ANTHRAX (See Chap. 183) Anthrax, caused by *Bacillus anthracis*, is primarily seen in cattle, sheep, horses, goats, and wild herbivores. Agricultural workers, stock breeders, butchers, and meat processors can become infected by contact with diseased animals. Contaminated hides, goat hair, wool, and bones can infect dockworkers, freight handlers, warehouse workers, and employees of processing plants that handle these products. Tanners, carpet makers, and upholsterers are also at risk. Anthrax spores are highly infectious, which makes the organism a desirable agent of germ warfare (see Chap. 213); laboratory workers handling specimens are also at risk.[5]

MYCOBACTERIAL INFECTIONS ***Cutaneous Tuberculosis.*** (See Chap. 184) Tuberculosis verrucosa cutis, a slow-growing warty papule or plaque caused by the inoculation of *Mycobacterium tuberculosis* or *M. bovis*, has been reported in pathologists and morgue attendants (prosector's or anatomist's wart). Surgeons, veterinarians, farmers, and butchers are also at risk, although the condition is rare at the present time.

Nontuberculous Mycobacterial Infections. *M. marinum* causes swimming pool or fish tank granuloma, a solitary or disseminated granulomatous infection seen in fishermen, fish tank cleaners (Fig. 212-1), and workers cleaning contaminated swimming pools. Surgeons are also at risk.

BRUCELLOSIS (See Chap. 183) Brucellosis is a zoonosis transmitted to humans from contact with infected animals or ingestion of untreated milk or milk products. Farmers, livestock breeders, meatpackers, veterinarians, and laboratory workers are at risk. An epidemic caused by sniffing bacterial cultures has been reported.[6]

TULAREMIA (See Chap. 183) Tularemia is caused by *Francisella tularensis*, a Gram-negative bacillus transmitted by ticks, fleas, and deerflies. Animal reservoirs include wild rabbits, squirrels, birds, sheep, beavers, muskrats, and domestic dogs and cats. Tularemia is seen in hunters, trappers, game wardens, butchers, fur handlers, and laboratory workers. It is highly infectious, and great care should be exercised in handling infected tissues and excreta.

OCCUPATIONAL SKIN DISEASES DUE TO BIOLOGIC, PHYSICAL, AND CHEMICAL AGENTS AT A GLANCE

- Certain occupations are associated with an increased risk of infection (viral, bacterial, fungal, parasitic) or arthropod bites, stings, or infestations.
- Mechanical trauma is common in the workplace and can have skin manifestations.
- Pre-existing skin conditions may be aggravated by work-related mechanical trauma.
- Occupational skin granulomas can be immunogenic (e.g., beryllium induced) or nonimmunogenic (e.g., silica induced).
- Occupational skin diseases can result from excessive heat, cold, and other atmospheric factors such as low humidity in the workplace.
- Exposure to silica, vinyl chloride, and other chemical agents can cause systemic sclerosis and limited scleroderma-like disease.
- Occupational chloracne is one of the most sensitive indicators of toxic exposure to halogenated aromatic hydrocarbons.
- Occupational skin cancers due to exposure to chemical carcinogens or to ultraviolet light are a major health concern.

ERYSIPELOID (See Chap. 183) Erysipeloid is almost always an occupational disease and is caused by *Erysipelothrix rhusiopathiae*, a Gram-negative rod that infects freshwater and saltwater fish, ducks, emus, turkeys, chickens, and other farmed animals such as sheep.[7]

TABLE 212-1
Occupational Skin Infections

Occupational Groups at Risk	Infections
Agricultural workers, farmers, shepherds, cattle workers, ranchers, animal scientists, animal breeders	Orf, milker's nodules, dermatophyte infections, mycetoma, chromoblastomycosis, sporotrichosis, cutaneous larva migrans
Butchers, meat handlers, abattoir workers	Staphylococcal and streptococcal infections, cutaneous anthrax, viral warts, erysipeloid, tularemia, brucellosis, leptospirosis
Construction and other outdoor workers	Blastomycosis, coccidiomycosis, arthropod bites
Cooks, bakers, food handlers, dishwashers, cannery workers, bartenders, others doing wet work	Candidal intertrigo and paronychia
Fish merchants and fishermen	Staphylococcal and streptococcal infections, erysipeloid
Foresters, hunters	Tularemia, Lyme disease
Gardeners	Sporotrichosis
Hairdressers, manicurists	Staphylococcal and streptococcal infections
Health care workers (physicians, nurses, dentists, physician and dental assistants, respiratory therapists, paramedics)	Herpes simplex, HIV infection, hepatitis, staphylococcal and streptococcal infections, candidiasis
Laboratory workers	Brucellosis, tularemia, HIV infection, hepatitis, monkeypox
Military personnel	Staphylococcal and streptococcal infections, dermatophyte infections, arthropod bites, leishmaniasis
Pet shop workers, aquarium handlers, fish tank cleaners	Fish tank granuloma (*Mycobacterium marinum*), monkeypox
Veterinarians	Cutaneous tuberculosis, cutaneous anthrax, brucellosis, tularemia, orf

HIV = human immunodeficiency virus.
Adapted from refs. 1–27.

Butchers, fishermen, and retailers of fish and poultry are commonly affected.

Viral Infections

HERPES SIMPLEX (See Chap. 193) Infection with herpes simplex virus (HSV) is the most common viral infection of occupational origin. Infections due to HSV type 1 or 2 are seen in occupations in which there is exposure to infected secretions from the mouth or the respiratory tract. Dentists, dental assistants, nurses, and respiratory technicians are particularly vulnerable, and herpetic whitlow is a common problem.[8] Infection with HSV-1 after a needle-stick injury has also been reported.[9] Herpes labialis is a common problem in woodwind and brass instrumentalists.[10] HSV infection on the body surfaces of wrestlers and rugby players, known as *herpes gladiatorum*, is temporarily disqualifying for infected athletes. In health care professions, the use of protective gloves, safety glasses, and masks are the best preventive measure and reduce the incidence of the infection.

▲ **FIGURE 212-1** Sporotrichoid atypical mycobacterial infection with *Mycobacterium marinum* in a woman who worked in a shop selling tropical fish.

HEPATITIS AND HUMAN IMMUNODEFICIENCY VIRUS INFECTION Needle-stick injuries are a well-recognized occupational hazard for health care workers, putting them at risk of acquiring an infectious disease from blood-borne pathogens. The average risk of human immunodeficiency virus (HIV) transmission after a percutaneous exposure to HIV-infected blood has been estimated to be approximately 0.3 percent.[11,12] For hepatitis B, the risk of clinical hepatitis if the blood was positive for both hepatitis B surface antigen and hepatitis B e antigen is reported to be 22 percent to 31 percent; the risk is 1 percent to 6 percent if the blood was positive for hepatitis B surface antigen but negative for hepatitis B e antigen.[12] A 95 percent decline in hepatitis B virus infection in health care workers was noted from 1983 to 1995, largely due to widespread immunization of health care workers with the hepatitis B vaccine.[13] The average incidence of anti–hepatitis C virus seroconversion after accidental percutaneous exposure to a hepatitis C virus–positive source is 1.8 percent (range, 0 percent to 7 percent).[12] The most accurate data on needle-stick and sharps injuries are derived from prospective studies, which yield an estimated annual incidence ranging from 562 to 839 injuries per 1000 health care workers per year.[14] Nurses have the most patient contact, and it is not surprising that this occupational group accounts for most reported cases.[14,15] Immediate evaluation of the injured employee is necessary to assess the risk related to exposure and the need for post-exposure prophylaxis (antiretroviral therapy for HIV, immunoglobulins and vaccination for hepatitis B virus). A substantial reduction in needle-stick injuries with the use of needleless systems or newer safety needle devices has been noted.[13] Needleless systems provide an alternative to needles for the specified procedures and thereby reduce the risk of percutaneous injury involving contaminated sharps. Examples of needleless systems include, but are not limited to, intravenous medication delivery systems that administer medication or fluids through a catheter port or connector site using a blunt cannula or other non-needle connection, and jet injection systems that deliver subcutaneous or intramuscular injections of liquid medication through the skin without the use of a needle.

VIRAL WARTS (See Chap. 196) Handlers of meat, poultry, and fish have a high prevalence of viral warts, which is likely attributable to the acquisition of minor cuts and abrasions during work. Human papillomavirus 7 has been isolated more frequently in this group of patients.[16]

MOLLUSCUM CONTAGIOSUM (See Chap. 195) Professional wrestlers and boxers are prone to developing molluscum.

ORF (ECTHYMA CONTAGIOSUM) (See Chap. 195) Orf, caused by a parapoxvirus, is

endemic in sheep and goats, and is easily transmitted to humans through direct contact. Veterinarians, farmers, and shepherds are at risk.

MILKER'S NODULES (See Chap. 195) The paravaccinia virus, which infects the udders of cows and produced ulcers in the mouths of calves, can be transmitted to dairy farmers and veterinarians, causing milker's nodules (or pseudocowpox)[17] (see eFig. 212-1.1 in on-line edition).

MONKEYPOX (See Chap. 195) An outbreak of human monkeypox in the United States in 2003 was traced to a shipment of infected exotic African rodents, some of which escaped, that produced secondary infection in wild prairie dogs housed at the same pet store. Exposure to these infected prairie dogs resulted in 37 human infections involving exotic pet dealers, pet owners, and veterinary care workers.[18] Although human-to-human transmission of monkeypox virus is thought to be low, the Centers for Disease Control and Prevention recommends strict contact, droplet, and airborne precautions for health care workers. Smallpox vaccination is recommended for health care workers and household contacts of confirmed monkeypox cases per Centers for Disease Control and Prevention guidelines.

Fungal Infections

DERMATOPHYTIC SKIN INFECTIONS (See Chap. 188) Dermatophytic skin infections are seen more frequently in farmers and animal husbandry workers.[19] Infections with *Trichophyton rubrum* and *T. mentagrophytes*, which are seen in the general population, may occur in work situations involving increased perspiration and occlusion. *Microsporum gypseum*, *T. mentagrophytes*, and *T. verrucosum* cause infection in agricultural and other outdoor workers (see eFig. 212-1.2 in on-line edition). *M. canis* infects veterinarians and laboratory workers. Physiotherapists who perform hydrotherapy are also more likely to develop fungal skin infections.[20] An unusual tinea corporis infection in a scientist due to a laboratory strain of *Arthroderma benhamiae* has been reported.[21]

CANDIDIASIS (See Chap. 189) Infection with *Candida albicans* is common in occupations that expose the skin to moisture and occlusion, such as those that require wearing gloves for long periods of time. Food handlers, nurses, dental assistants, dishwashers, and laundry workers are at risk.

SPOROTRICHOSIS (See Chap. 190) Sporotrichosis, caused by *Sporothrix schenckii*, is acquired by inoculation through puncture wounds from thorns, sticks, or splinters. It is seen in farmers, nursery and forestry workers, and those in other outdoor occupations. Gardeners working with sphagnum moss used for packing plant roots may also be at risk.

MYCETOMA (MADURA FOOT) (See Chaps. 185 and 190) Mycetoma, caused by various species of fungi and actinomycetes, is seen mainly in farmers and outdoor workers in tropical and sub-tropical countries; walking barefoot is a risk factor.

CHROMOBLASTOMYCOSIS (See Chap. 190) Chromoblastomycosis, a deep mycosis, often follows a puncture wound or other trauma during which soil-inhabiting fungi of *Phialophora*, *Hormodendrum*, and *Fonsecaea* species are injected deep into the tissues. Agricultural and other outdoor workers are at risk.

BLASTOMYCOSIS (See Chap. 190) Those at risk of blastomycosis include agricultural, forestry, and construction workers; farmers; and persons working with heavy earth-moving equipment.[22]

COCCIDIOIDOMYCOSIS (See Chap. 190) Coccidioidomycosis is acquired by the inhalation of dust containing the spores of *Coccidioides immitis*. Farmers, construction workers, bulldozer and heavy equipment operators, and laboratory workers are susceptible.

Parasitic Diseases (See Chaps. 206 and 207)

There has been an increase in the incidence of cutaneous leishmaniasis in U.S. military personnel who were deployed to southwest or central Asia or other areas in which leishmaniasis is endemic.[23,24] The larvae of *Ancylostoma braziliense* and *Necator americanus* cause creeping eruption (cutaneous larva migrans) in agricultural workers, fishermen, sewer workers, and lifeguards. Skin divers, lifeguards, dockworkers, and caretakers who maintain lakes and ponds are prone to development of swimmer's itch caused by the cercariae of a schistosome; there is also a report of swimmer's itch developing after cleaning of an aquarium.[25] Dogger Bank itch is seen in fishermen and dockworkers in the North Sea, who are exposed to the marine bryozoan *Alcyonidium gelatinosum*.

Arthropod Stings, Bites, and Infestations (See Chaps. 208 and 210)

The bites of bees, wasps, hornets, ants, ticks, mites, centipedes, and millipedes frequently cause work-related skin disease. Outdoor workers, food handlers, chicken farmers (chicken mites), workers in food-processing plants, restaurant workers, and dockworkers may be affected. Epidemics of scabies have occurred in nursing homes, hospitals, and other residential facilities for the aged.[26] Lyme disease (see Chap. 187) is transmitted through a tick bite and can affect outdoor workers, loggers, ranchers, and construction workers in wilderness areas.[27]

SKIN DISEASES DUE TO PHYSICAL AGENTS

Mechanical Trauma–Induced Skin Disorders

The skin may be subjected to friction, pressure, cuts, lacerations, and abrasions in the workplace. Repeated mechanical trauma such as low-intensity pressure or friction, the most common mechanical trauma, leads to hyperpigmentation and lichenification, whereas heavier and persistent friction leads to hyperkeratosis and callus formation (Fig. 212-2). Sudden shearing forces may lead to the formation of friction blisters, erosions, or ulcers.[28] Prolonged and excessive pressure may produce hyperpigmentation and thickening, characteristic as the stigmata of various occupations[29] (Fig. 212-3). Besides calluses and corns, occupational marks include discolorations, telangiectases, tat-

▲ **FIGURE 212-2** In spite of the growing automation of many jobs, the hands are still useful tools. Here a body shop worker is sanding a fender in preparation for painting.

▲ **FIGURE 212-3** Nail dystrophy in a slaughterhouse worker. While holding a knife in his right hand to cut off the hide, he pulled and tugged on the hide with his left hand. Note the calluses over the distal interphalangeal joints on the left.

toos, and deformities. Greater automation and better protective clothing, especially a wider selection of gloves, have decreased the incidence of occupational marks. In musicians, clinical presentation and location of skin lesions are usually specific for the instrument used (e.g., fiddler's neck, cellist's chest, guitar nipple, flautist's chin).[10] In athletes, repetitive trauma from running may lead to black heel or *talon noir* as well as blisters and jogger's toe.[30] Corns may also develop due to extreme pressure associated with bony deformities, poor foot mechanics, or improper footwear.[31] A new group of skin disorders related to prolonged computer use leading to repetitive trauma (mousing callus) and prolonged pressure (computer palms) has been described.[32,33] Underlying skin conditions in patients such as psoriasis and lichen planus may be aggravated by occupational trauma (koebenerization). Preexisting dermatitis caused by friction and pressure may predispose to the development of allergic sensitization.[34]

Hyperkeratotic hand eczema is a chronic hyperkeratotic, scaly, fissured dermatitis involving the palms seen in workers engaged in manual work involving repeated friction and pressure (Fig. 212-4). Pulpitis, a dry, scaly, fissuring, painful dermatitis, may be seen on the fingertips, especially in women engaged in domestic work.[35] A similar condition may be seen in dental personnel allergic to acrylates, in which paresthesias of the fingertips are reported. Post-traumatic eczema (dermatitis in loco minoris resistentiae) is dermatitis at the site of cutaneous trauma. The eczema usually develops within a few weeks of the acute injury and may persist or recur for long periods of time.[35] The damage and functional alteration of the skin is thought to play a role in precipitating the eczema. Table 212-2 lists the types of post-traumatic eczema and provides some examples.[36]

Granulomas

Granulomas may form due to penetration of the skin by foreign material; they may be immunogenic or nonimmunogenic. Table 212-3 lists causes of occupational skin granulomas.[37] The penetration of human hair into the interdigital spaces of barbers and of cow and sheep hair into the hands of animal tenders can produce foreign-body granulomas.[38]

▲ **FIGURE 212-4** Chronic hypertrophic dermatosis of the palms in a 59-year-old machinist. He was transferred to work in a storeroom, where he continually handled tools, and was forced to retire because of persistence of the dermatosis with its fissuring and bleeding.

TABLE 212-2
Clinical Classification of Post-Traumatic Eczema

1. Idiopathic reaction (endogenous eczema absent) (e.g., thermal burn on hand followed by eczema 1 mo later)
2. Isomorphic reaction
   a. Primary (precedes endogenous eczema) (e.g., laceration on finger followed by finger eczema and later by flexural atopic eczema)
   b. Secondary (follows endogenous eczema) (e.g., irritant hand eczema followed by finger puncture and finger eczema, which persists after hand eczema clears)

From Mathias CGT: Post-traumatic eczema. *Dermatol Clin* **6**:35, 1988.

Thermal Burns and Other Heat-Induced Skin Disorders

Workers are at risk for thermal burns as a result of scalding; contact with liquid metal, hot equipment, and tar; and flame burns after explosions. Kitchen workers and adolescents working in fast food restaurants may develop scalds from hot grease.[39] Roofers frequently incur hot tar burns, whereas explosives

TABLE 212-3
Classification of Occupational Granulomas

Causative Substance (Setting)

Immunogenic Granulomas
- Beryllium (metal production, x-ray screen production)
- Zirconium (steel working)
- Cadmium (paint and rubber industry)

Nonimmunogenic Granulomas
- Silica (sandblasting, mining, land mine explosions)
- Starch (occupations requiring the use of surgical gloves)
- Cactus spines (farming, outdoor work)
- Sea urchin spines (diving)
- Wood splinters (farming, forestry)
- Hair (hairdressing, farming, animal handling)
- Sheep wool (sheep raising)

Adapted from Goh CL: Non-eczematous occupational contact reactions, in *Condensed Handbook of Occupational Dermatology*, edited by Kanerva L et al. Berlin, Springer-Verlag, 2004, p 135.

and flammable liquids cause most industrial burns. Persons working in foundries and smelting plants are at risk for molten metal burns. Firefighters are also at risk, although the use of protective gear reduces the extent of burn injuries.[40] Workers experiencing prolonged or repeated exposure to heat can develop erythema ab igne. Acne vulgaris, rosacea, and herpes simplex may be aggravated by the heat of open furnaces, heat torches, ovens, and stoves. Heat-induced urticaria may result from strenuous physical exercise.

Electrical Burns

In industrial settings, electrical burns are usually high-voltage injuries, which may result in serious tissue destruction. Outdoor workers are at a risk for lightening burns, which show characteristic fern-like patterns.

Cold-Induced Skin Disorders (See Chap. 93)

Frostbite, chilblains, immersion foot, and cold urticaria are common in workers employed in cold environments, such as military personnel stationed in cold climates. Ice makers, liquefied gas makers, refrigeration workers, and persons engaged in winter sports are also at risk.

Vibration Syndrome

The vibration of hand-held tools may induce a type of vascular spasm in the fingers and hands known as *white fingers* or *vibration-induced white finger*.[41] Operators of vibrating impact and power tools such as jackhammers, pounding machines, riveting hammers, chain saws, and hand grinders may develop this condition, especially in cold climates. The vascular symptoms may be associated with neuromuscular symptoms and even with bony changes, collectively known as *hand-arm vibration syndrome*.[42] Earlier symptoms are mild and consist of numbness and tingling, followed by blanching and stiffness of one or more fingers, with paresthesias and weakening of intrinsic muscles developing in the later stages. Vibration frequencies between 30 and 300 Hz are most strongly associated. Smoking is also considered a risk factor. Improvements in the design of chain saws and other vibrating tools has resulted in a decrease in the prevalence of vibration-induced symptoms.

SKIN DISEASES DUE TO CHEMICAL AGENTS AND RADIATION

Occupational Connective Tissue Disorders

Raynaud phenomenon and scleroderma-like skin lesions with osteolytic changes in the bones of the fingers are well described in vinyl chloride workers (see also Chaps. 158 and 171).[43] The syndrome has been called *occupational acro-osteolysis*. Exposure to other organic solvents has also been reported to cause scleroderma-like disease (Table 212-4).[43] Systemic sclerosis and scleroderma-like skin changes are also associated with silica exposure and pulmonary silicosis, especially in underground miners (coal, gold, uranium, lead miners), stone masons, and those in related occupations. The simultaneous operation of vibrating tools during mining may contribute to the development of the disease.

Occupational and Environmental Acne

OIL ACNE (See Chap. 78) Oil acne is a folliculitis occurring on skin that comes in contact with oils, especially heavy industrial oils or straight cutting oils used by machinists. Areas with the greatest exposure to oil-soaked clothing, such as the arms and thighs, are most frequently involved. Oil acne is also caused by airborne oil mist.[44] With better engineering controls and protective clothing, the occurrence of oil acne has decreased.

COAL TAR AND PITCH ACNE (See Chap. 78) Coal tar oils, creosote, and pitch can produce a comedonal type of acne, with a predilection for exposed areas, particularly the malar regions.[45] Coal tar plant workers, roofers, road maintenance workers, and construction workers are at risk. A phototoxic reaction may also occur and cause hyperpigmentation, known as *coal tar melanosis*. Pitch and tar papillomas, keratoses, and acanthomas may develop as a late complication.[46]

CHLORACNE (See Chap. 78) Chloracne is one of the most sensitive indicators of occupational or environmental exposure to certain toxic halogenated aromatic hydrocarbons, which occur as trace contaminants during synthesis of industrial chemicals. Exposure can be percutaneous or by inhalation or ingestion. One of the most potent inducers of chloracne is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), which has been identified in multiple industrial outbreaks as well as in putative poisoning cases in Austria and the Ukraine.[47] Other chloracnegenic chemicals are listed in Table 212-5.[48]

Clinically, the distribution is characteristic, with multiple closed comedones and straw-colored cysts primarily over the malar crescents and retroauricular folds, sparing the nose; the posterior neck, trunk, and extremities as well as the buttocks, scrotum, and penis may also become involved. TCDD impairs differentiation of keratinocytes.[49] Polychlorinated biphenyls (PCBs) and TCDD cause follicular hyperkeratosis and palmo-plantar hyperhidrosis. PCBs can also cause skin, mucus membrane, and nail hyperpigmentation as well as conjunctivitis. Based on clinical findings alone, it may be difficult to differentiate chloracne from early acne vulgaris (Table 212-6) and senile (solar) comedones. Scarring may be mild to severe, depending on the degree of chemical exposure and skin involvement.[47,50]

Occupational Skin Cancer

The first cancer to be linked to an environmental exposure was scrotal cancer in chimney sweeps, reported by Sir Percivall Pott in 1775. The percentage of skin cancers induced by the work environment is disputed; some studies suggest that it is as high as 70 percent to 80

TABLE 212-4
Substances Associated with Occupational Connective Tissue Diseases

Systemic Sclerosis
- Silica
- Chlorinated and aliphatic hydrocarbons and solvents (e.g., trichloroethylene)
- Aromatic hydrocarbons and solvents (e.g., benzene)

Scleroderma-Like Disease
- Vinyl chloride
- Epoxy resins [bis(4-amino-3-methylcyclohexyl)methane]
- Chlorinated and aliphatic hydrocarbons and solvents (e.g., trichloroethylene)
- Aromatic hydrocarbons and solvents (e.g., benzene)
- Pesticides
- Drugs (bleomycin, pentazocine)
- Aniline and fatty acid anilides
- Paraffin
- Silicon

TABLE 212-6
Clinical Features of Acne Vulgaris Compared with Those of Chloracne

Clinical Feature	Acne Vulgaris	Chloracne
Usual age of occurrence	Teenage	Any
Comedones	Present	Many (if absent, not chloracne)
Straw-colored cysts	Rare	Pathognomonic
Temporal comedones	Rare	Diagnostic
Retroauricular involvement	Uncommon	Common
Nose involvement	Uncommon	Uncommon
Associated systemic findings	Rare	Common

percent,[52] but other studies indicate a much lower percentage.[53] The common causative agents implicated in occupational skin cancers and occupations with potential exposure are listed in Table 212-7.

ULTRAVIOLET LIGHT (See Chaps. 112 and 113) Ultraviolet (UV) radiation acts as both a tumor initiator and tumor promoter. Most studies report a significant association between work-related sun exposure and skin cancer[55] as well as actinic keratoses[56] (see eFig. 212-4.1 in on-line edition), but other studies have found no definite association[57] or a very slight increased risk,[58] perhaps because of greater self-selection for indoor jobs among those with fair skin and a tendency to burn compared to those with less-susceptible skin types.[57]

Exposure to UV radiation, particularly UVB light, is thought to play a critical role in the pathogenesis of malignant melanoma (see Chap. 124),[59] although some studies do not show an increased risk of developing melanoma in outdoor workers compared to indoor workers.[60] This is consistent with the epidemiologic link of melanoma to intermittent intense UV exposures, more often experienced in association with vacations or recreational activities than employment. Non-occupational exposures to nonsolar radiation, such as UV lamps and sunbeds, is reportedly associated with an increased risk of melanoma.[61]

The association between squamous cell carcinoma (see Chap. 114) and cumulative UV exposure is stronger, which makes outdoor occupations a significant risk factor. However, other occupational exposures, such as exposure to chemical carcinogens, may also play a critical role,[62] and an additive effect cannot be excluded.

To determine the role that the workplace plays in the development of actinic skin damage and skin cancer, the physician must consider the detailed occupational history with job descriptions beginning with the first job, as well as non-occupational activities, hobbies and sports, and other recreational pursuits, including those in which the patient engaged at a younger age.

POLYCYCLIC AROMATIC HYDROCARBONS Exposure to polycyclic aromatic hydrocarbons (PAHs) accounts for most of the reported occupational skin tumors.[63] PAHs are hydrophobic, nonpolar compounds that form DNA adducts[61] and act as complete carcinogens.[64] Coal tar and petroleum products such as tar, pitch, coke, carbon black (soot), creosote, anthracene, crude paraffin, asphalt, fuel and diesel oils, lubrication and coolant oils, and untreated mineral oils, as well as oils, waxes, and tars from the distillation products of shale oil and lignite, contain PAHs.[65] High occupational exposures to PAHs can occur in several industries and occupations (see Table 212-7), and workers can be exposed to PAHs through inhalation or skin contact. The risk for melanoma, as well as internal cancers, has been reported to be increased in oil refinery workers.[66]

An association between scrotal cancers and the use of cutting oils has been noted, probably related to the addition of shale oil.[67] Creosote used in wood treatment has been suggested as a cause of skin and lip cancer when associated with sunlight exposure.[68] Roofers and road pavers are also at increased risk for skin cancers and internal cancers due to the potential carcinogenicity of bitumen and of PAHs from coal tar products.[69] Tar refinery workers are at increased risk of developing non-melanoma skin cancers, mainly on facial areas, forearms, and hands.[70] Use of topical tar products to treat dermatologic disease has been suggested to pose a skin cancer risk but has never been documented to do so.

ARSENIC Arsenic-containing drinking water is clearly associated with various

TABLE 212-7
Agents Inducing Occupational Skin Cancers and Industries Presenting Exposure Risk

Causative Agent	Industries/Activities with Potential Exposure
Polycyclic aromatic hydrocarbons	Coal gasification, aluminum production, iron and steel foundries, coke production, shale oil extraction, tar distilling, asphalt and roofing material work, wood impregnation
Arsenic	Glass working; copper, zinc, and lead smelting; pesticide and herbicide production; semiconductor industry
Ultraviolet light	Outdoor work, welding
Ionizing radiation	Nuclear power plants, radiography, uranium mining

Adapted from refs. 51–75.

▲ **FIGURE 212-5** Radiodermatitis and squamous cell carcinoma in a woman who had worked as an x-ray technician for years, holding young patients still during x-ray examinations, including fluoroscopy, but without protection.

skin and internal organ malignancies.[71] The methylated, trivalent form of arsenic is more toxic than the pentavalent form.[72] Although arsenic induces chromosomal abnormalities in experimental systems and human tissues, it does not induce cancers in animal models.

Long-term arsenic exposure may lead to arsenical keratosis, squamous cell carcinoma, and basal cell carcinomas, and Bowen disease. Merkel cell carcinoma has also been reported in a person with chronic arsenicalism.[73] Table 212-7 lists occupations at risk for exposure to arsenic.

IONIZING RADIATION (See Chap. 95) Exposure to ionizing radiation has been known to be a cause of occupational skin cancer since the early 1900s. Atomic bomb survivors have an increased risk of developing basal cell carcinoma.[74] X-ray–induced skin cancers appear to be associated with a higher frequency of multiple skin lesions, recurrences, and major surgical sequelae[75] (Fig. 212-5). There have been reports of a high prevalence of melanoma among airline pilots and flight attendants exposed to cosmic radiation; however, some observers feel that this association is due to lifestyle effects.[76]

DIAGNOSIS, TREATMENT, AND PREVENTION

General concepts in the diagnosis, treatment, and prevention of occupational skin disorders are discussed in Chap. 211.

SECTION 35

THE SKIN IN BIOTERRORISM AND BIOLOGIC WARFARE

CHAPTER 213

Cutaneous Manifestations of Biologic, Chemical, and Radiologic Terrorism Attacks

Scott A. Norton

The bombings of the World Trade Center's twin towers on September 11, 2001 and the spate of anthrax cases that soon followed introduced new responsibilities to the medical and public health communities.[1–3] Physicians now have a societal responsibility to know the principles of responding to outbreaks of disease caused by biologic weapons. The dermatologist's role in recognizing bioterrorism is particularly significant because many pathogens produce illnesses with prominent cutaneous findings.[4] The dermatologic aspects of smallpox, for example, are the most obvious and dramatic aspects of the disease. Other conditions, such as anthrax, frequently—although not always—manifest in the skin. It is likely that the diagnosis of an index case of a bioterror outbreak will rest on dermatologic findings, subtle or overt.

Public health authorities recognize that terrorism may involve other sorts of unconventional weapons, including chemical and radiologic weapons. This chapter provides an overview of the manifestations of unconventional weapons that terrorists might use.

BIOLOGIC WEAPONS

The Centers for Disease Control and Prevention (CDC) stratified potential bioweapons into three levels of risk (Tables 213-1 through 213-3) based on ease of manufacture, ease of dissemination, subsequent person-to-person transmission, lethality, and psychosocial effects (literally, how terrified a community will be). When an organism is intentionally dispersed as part of warfare, terrorism, or criminal activity, a goal is to infect huge numbers of people. Hence, the dispersal system may be engineered to disseminate the disease widely, often as airborne spread that results in pulmonary or inhalational disease. Some—but not all—of the pathogens are then transmissible from person to person, thereby potentiating the public health effects of—and the terror associated with—biologic weapons.

Category A Agents and Diseases

ANTHRAX (See Chap. 183) In late 2001, an outbreak of 22 cases in several states along the eastern seaboard of the United States was due to an intentional, criminal act of bioterrorism.[10,11] The outbreak occurred when envelopes of spores were distributed through the postal system, contaminating many offices and infecting mail handlers and letter recipients. Initially, it was thought the spores were finely engineered into an easily aerosolized form, but more recent examinations suggest that even crudely milled spores could cause such an outbreak. The easy weaponization of this highly lethal agent makes it one of the most feared biologic weapons. During the Cold War, several nations were known to have produced massive quantities of weaponized anthrax, evidence of which became widely known after a 1979 mishap at the Soviet Union's Sverdlosk bioweapon facility. A cloud of anthrax spores was accidentally released and dozens of people downwind died from inhalational anthrax. The Sverdlosk

BIOLOGIC, CHEMICAL, AND RADIOLOGIC TERRORISM ATTACKS AT A GLANCE

- Potential biologic weapons are classified by the Centers for Disease Control and Prevention into Category A, B, and C levels of risk.
- Category A comprises smallpox, anthrax, plaque tularemia, botulism, and viral hemorrhage fevers.
- Category B comprises a large number of pathogens ranging from brucellosis to listeria and *Clostridium perfringens*.
- Category C comprises a number of viruses, rickettsioses, multidrug-resistant tuberculosis, and rabies.
- Chemical weapons are categorized into blistering agents (such as sulfur mustard), nerve agents, blood agents, urticating agents, and incapacitating agents.
- Radiologic weapons include what is called a *dirty bomb*, which produces low levels of radiation contaminating an entire zone.

TABLE 213-1
Biologic Agents or Diseases Most Likely to Be Used in Terrorism or Warfare (Centers for Disease Control and Prevention and National Institutes of Health Category A Agents or Diseases)[a]

Disease	Pathogen or Agent	Weaponized Route of Transmission	Cutaneous Findings	Percent with Cutaneous Findings in Bioterror Attack	Chapter in *Dermatology in General Medicine*
Smallpox	*Variola*	Airborne, then person to person.	Enanthem followed by classic vesicopustular eruption.	All.	195
Anthrax	*Bacillus anthracis*	Airborne. No person-to-person transmission.	Edematous papule or plaque evolving into an ulcer surmounted by a black eschar.	Roughly 50%, based on 2001 experience.	183
Plague	*Yersinia pestis*	Airborne, then person to person.	None in pure pulmonary form. Distal purpura and gangrene in septicemic form. Buboes in bubonic form.	Not known.	183
Tularemia	*Francisella tularensis*	Airborne without subsequent person-to-person transmission.	None in pure pulmonary form. Membranous pharyngitis and oropharyngeal ulcers in oropharyngeal form. Ulceroglandular syndrome.	Not known.	183
Botulism	Toxin produced by *Clostridium botulinum*	Airborne, less likely through intentional contamination of food or water. No person-to-person transmission.	Cranial nerve palsies followed by descending paralysis that spares sensation and cognition. Xerostomia, facial palsies, pupils fixed and dilated.	Possibly 100% will have xerostomia, facial palsies, and fixed and dilated pupils.	183
Viral hemorrhagic fevers	Examples include filoviruses, such as Ebola and Marburg; arenaviruses, such as Lassa, Junin, and Machupo; flaviviruses, such as dengue; and bunyaviruses, such as hantavirus and Rift Valley fever	Airborne, then possible subsequent transmission depending on agent. Dengue, for example, is transmitted by the mosquito *Aedes aegypti.*	Petechiae, purpura, and frank hemorrhage.	Not known.	—

[a]Category A diseases or agents are the highest priority because they can be easily disseminated or transmitted from person to person; result in high mortality rates and have the potential for major public health impact; might cause public panic and social disruption; and require special action for public health preparedness.

disaster, however, led to the notion that weaponized anthrax caused only inhalational illness. The letter-borne anthrax incidents of late 2001 showed otherwise when only 11 of the 22 victims had inhalational disease, four of whom died. The others had cutaneous anthrax.

Inhalational disease can have longer incubation periods than cutaneous disease, perhaps as long as to 40 to 60 days. If a person is on antibiotics (for another reason or for anthrax prophylaxis), *Bacillus anthracis* may remain in its more protected spore form until the antibiotics are discontinued. The initial symptoms of inhalation anthrax are flu-like and non-specific, characterized by fever, fatigue, and malaise, but soon followed by chills, high fever, nonproductive cough, and dyspnea. Cyanosis, shock, multiorgan failure, and death may ensue. Chest radiographs characteristically show symmetric mediastinal widening due to hemorrhagic lymphadenitis of mediastinal nodes. In inhalational disease, as well as in septicemic anthrax, which may follow cutaneous or gastrointestinal anthrax, bacteremia may lead to fulminant meningitis.[10,11,14,15]

Clinical Findings. Patients with inhalational anthrax often present initially with a flu-like illness that progresses virulently into severe febrile illness accompanied by tachypnea, stridor, and cyanosis. In inhalation anthrax, the chest x-ray shows significant mediastinal widening and hilar adenopathy because of edema and hemorrhagic necrosis of draining nodes. The pulmonary parenchyma is usually spared, hence the disease is identified as *inhalational anthrax*, not pulmonary anthrax.[12]

Diagnosis. The acute onset of a painless edematous noduloulcerative lesion with a black eschar should elicit the possible diagnosis of cutaneous anthrax, especially in the epidemiologic setting of exposure to imported animal products, recent travel to endemic areas, or presence of known use of weaponized anthrax (see Fig. 183-1 in Chap. 183; Table 213-4).[16] An additional clinical clue is the presence of edema vastly out of proportion to the observed size of the lesion. Diagnostic steps include obtaining swabs of exudates for Gram stain and culture, biopsy specimens for histopathology and immunohistochemical staining, and to draw blood samples for culture and serology. The CDC requests that practitioners notify local or state health departments before attempting a laboratory diagnosis of cutaneous anthrax.

The diagnosis is usually suspected on the basis of the character of the lesion and the hobby exposure, occupational history, or likelihood of bioterrorism. Demonstration of large Gram-positive rods in vesicle fluid on aspiration beneath the eschar, or on skin punch biopsy, also using a direct fluorescent antibody technique supports the diagnosis. Definitive diagnosis requires culture of the organism and demonstration of its susceptibility to

TABLE 213-2
Centers for Disease Control and Prevention and National Institutes of Health Category B Agents or Diseases[a]

Disease	Pathogen or Agent	Cutaneous Findings	Chapter in *Dermatology in General Medicine*
Brucellosis	*Brucella* sp.		183
Glanders	*Burkholderia mallei*		183
Melioidosis	*B. pseudomallei*		183
Typhus	*Rickettsia prowazekii*		199
Water safety threats	Examples include bacteria (e.g., *Vibrio cholerae),* viruses (e.g., Norwalk virus) and protozoa (e.g., *Cryptosporidium parvum)*	Usually none	
Food safety threats	Examples include *Listeria monocytogenes* and *Escherichia coli* O157:H7	Rare	
Psittacosis	*Chlamydia psittaci*	None	
Q fever	*Coxiella burnetii*	None	
Ricin poisoning	Prepared from *Ricinus communis* (castor beans)	None	
Staphylococcal enterotoxin B		None	
Viral encephalitis	Examples include α viruses that cause equine encephalitides	Rare	
Clostridium perfringens toxin	Epsilon toxin of *C. perfringens*	None	

[a]Category B diseases and agents are the next highest priority because they are moderately easy to disseminate; result in moderate morbidity rates and low mortality rates; and are not part of the Centers for Disease Control and Prevention's routine surveillance system.[5,6,8]

TABLE 213-3
Examples of Centers for Disease Control and Prevention and National Institutes of Health Category C Agents or Diseases[a]

- Nipah virus
- Hanta virus
- Tick-borne hemorrhagic fever virus, specifically Crimean-Congo hemorrhagic fever[b]
- Tick-borne encephalitis complex
- Yellow fever[b]
- Avian influenza virus and severe acute respiratory syndrome virus[c]
- Multidrug-resistant tuberculosis
- Rabies
- Other rickettsioses (e.g., those caused by *Rickettsia typhi, R. conori, R. rickettsia, Orientia tsutsugamushi*)

[a]Category C agents or diseases include emerging pathogens that could be engineered for mass dissemination in the future because of availability, ease of production and dissemination, and potential for high morbidity and mortality rates and major public health impact.[5,6,9] Category C agents and diseases generally lack specific dermatologic findings.
[b]Yellow fever virus and most hantaviruses can cause thrombocytopenia, hemorrhage, and hemodynamic instability that can lead to mucosal bleeding.
[c]The H5N1 strain of influenza A virus (avian influenza) and severe acute respiratory syndrome virus have the potential for rapid, widespread, human-to-human transmission, with high morbidity, mortality, and disruption to societal order.

specific bacteriophage lysis. Occasionally, the organism can be isolated from the blood during the acute cutaneous illness as well as in disseminated anthrax. Retrospective serodiagnosis is possible with the demonstration of a titer rise in electrophoretic-immunotransblots of antibody to protective antigen and enzyme-linked immunosorbent assay for detection of antibodies to lethal factor.

Differential Diagnosis.

Therapy. Naturally occurring anthrax is susceptible to penicillin and doxycycline but weaponized anthrax may have been engineered to be resistant to these antibiotics. Therefore, a fluoroquinolone such as ciprofloxacin is recommended for initial treatment of confirmed or suspected anthrax, even in pregnant women and children in whom this class of antibiotic is rarely administered. Once drug sensitivities have been established, the patient may be switched to another antibiotic as clinically indicated. Antibiotics kill activated *B. anthracis* bacilli but do not reverse the effects of toxins already produced.

Two types of vaccine are available for immunization against anthrax.[6] The first vaccine is licensed for human use in the United States to protect workers in occupations that might expose them to *B. anthracis*; it has been given to members of the Armed Forces of the United States since 1998. The vaccine is a sterile culture filtrate (primarily protective antigen) of an attenuated strain of *B. anthracis* adsorbed to an aluminum hydroxide adjuvant and administered in six doses over 18 months. The second vaccine is for immunization of livestock against anthrax and consists of viable spores of an attenuated, non-encapsulated, toxigenic strain.

PLAGUE (See Chap. 183) In nature, the disease is usually limited to enzootic cycles between rodent reservoirs and flea vectors. Most human infections occur via flea bites and typically lead to bubonic plague (see Chap. 183), which is highly lethal but generally not communicable to others. In naturally occurring disease, human-to-human transmission occurs mainly if the patient's condition changes from bubonic form of plague to the pneumonic form. Once in the lungs, the pathogens are dispersed within droplets that others inhale, leading to additional cases of pneumonic plague. This form of plague is more deadly than bubonic, having a fatality rate among untreated cases that approaches 100 percent. Hence, deliberate spread of aerosolized plague bacteria could kill massive numbers of people.

Pneumonic plague does not produce buboes, which are the result of transcutaneous transmission via flea bites. Instead, pneumonic plague produces skin lesions if it evolves into septicemic plague. Then the patient may develop acral ecchymoses and distal gangrene, often accompanied by disseminated intravascular coagulation. These lesions resemble purpura fulminans, septic emboli, or meningococcemic purpura, and possibly gave rise to the term *Black Death.*

Plague is caused by *Yersinia pestis*, an aerobic Gram-negative bacillus with "safety-pin" bipolar staining. It produces several intracellular plasmid-encoded toxins that function as virulence factors. Plague in any form is a reportable disease in every jurisdiction worldwide. Confirmatory labora-

TABLE 213-4
Diagnostic Algorithm for Suspected Cutaneous Anthrax

- The highest suspicion should be given to those lesions in which the patient had a known or highly suspected exposure to anthrax. However, as some of the recent cases have demonstrated, no known exposure had occurred when the patients presented for care.
- Notify your local Department of Health to inform them of the patient with suspected anthrax and to obtain any additional instructions before doing diagnostic tests. (A list of state Department of Health contacts can be found at http://www.cdc.gov/phppo by clicking on "State Public Health Locator"). Notify your local laboratory regarding suspected anthrax, and inform them that samples will be sent shortly.
- Diagnosis: Physicians should maintain universal precautions when evaluating patients with suspected cutaneous anthrax (mask is not required). Although contact with exudate should be avoided (as should contact with any blood or body fluid), physicians evaluating patients with suspected cutaneous anthrax are not considered at risk for contracting inhalational anthrax because the disease is acquired through contact with anthrax spores, not active bacteria. The laboratory evaluation should include the following:
  - Swab exudates for Gram stain and culture. The organism is best demonstrated when lesions are in the vesicular stage. If vesicles are present, soak two, dry, sterile Dacron- or Rayon- (not cotton) tipped swabs in vesicular fluid from a previously unopened vesicle. During the eschar stage, gently lift an edge of the eschar and rotate two swabs beneath the edge without removing the eschar. If neither vesicle nor eschar is present, swab the base of the ulcer with a sterile, moist, synthetic (Dacron or Rayon) swab. (Lesions usually become sterile within 24–48 h after starting antibiotics effective against *Bacillus anthracis*. Therefore, culture of lesions in patients on antibiotics may not yield bacterial growth.)
  - Obtain a full-thickness (through the entire dermis), 4-mm punch biopsy for permanent sections (formalin-fixed) for histologic evaluation, IHC studies, and PCR. A second sterile punch biopsy specimen can be obtained for Gram stain and bacterial culture and fungal and atypical mycobacterial stains and cultures if indicated (bacterial culturette or sterile non-bacteriostatic saline). Dividing a single biopsy specimen is not recommended.
    - If a vesicle is present, biopsy the edge of the vesicle and include adjacent non-vesicular skin.
    - If an eschar is present, biopsy the erythematous area immediately adjacent to the edge of the eschar. If possible, a second biopsy from the center of the eschar is useful.
    - If both a vesicle and eschar are present, a biopsy of each lesion is indicated.
    - Submitted specimens should be accompanied by information such as brief clinical history, description and chronology of the lesion(s), treatment, and date of biopsy in relation to antibiotic treatment. A photograph, digital image, or diagram indicating the site of each biopsy in relation to the lesion and descriptive details of the lesion would be extremely valuable.
    - The sample for permanent sections should be placed in formalin and shipped at room temperature. After preparing hematoxylin and eosin–stained slides,[a] the fixed tissue block should be saved by the dermatopathology laboratory for potential transfer to the CDC for histologic evaluation, IHC, and PCR.
    - The sample for culture should be transported immediately to the microbiology laboratory fresh in a sterile container or in a bacterial culture tube (e.g., a culturette) for immediate processing for Gram stain and bacterial culture, and fungal and atypical mycobacterial stains and cultures if indicated. (One may add sterile non-bacteriostatic saline to the container.)
  - Draw one 5-mL tube of blood into a red-topped or serum separator tube and transfer it to the laboratory for isolation of serum and subsequent storage of serum at –70°C (–94°F). Label the tube: "Anthrax serology. Store serum at –70°C for special pickup." A similar convalescent sample should also be drawn 3–4 wk later.
  - Draw one 5-mL tube of blood into a purple-topped tube. This tube should be refrigerated and held for pick up for potential PCR diagnostic tests by the CDC. Blood-based assays are currently in a state of development by the CDC. During your contact with your local laboratory or Department of Health office, ask them about the up-to-date blood-testing recommendations.
  - Obtain blood cultures for febrile or hospitalized patients. There is no need to perform nasal swabs unless directed by the public health authorities as part of an epidemiologic investigation.

CDC = Centers for Disease Control and Prevention; IHC = immunohistochemistry; PCR = polymerase chain reaction.
[a]Because the skin lesions of anthrax are caused by toxins, cutaneous anthrax is not ruled out by a negative culture or biopsy.
From Carucci JA et al: Cutaneous anthrax management algorithm. *J Am Acad Dermatol* **47**:766, 2002, with permission.

tory tests include culture of *Y. pestis* from a clinical specimen or detection by polymerase chain reaction. Serologic tests are not useful in the acute setting.[18]

An inactivated whole-cell plague vaccine is administered to people who have potential occupational exposure to infected rodents (e.g., wildlife biologists and American military personnel). The primary immunization series requires three intramuscular doses administered over 6 months with boosters every 1 to 2 years if indicated. Animal challenge studies suggest that the plague vaccine is more protective against bubonic (flea-borne) plague than it is against airborne pathogens or pneumonic plague.

In the event of an outbreak of pneumonic plague, the keystone of protection is isolation of cases and close contacts, as well as the use of prophylactic antibiotics, specifically doxycycline, a quinolone such as ciprofloxacin, or chloramphenicol. For treating cases, the preferred agents are streptomycin or gentamicin, although doxycycline, ciprofloxacin, and chloramphenicol are acceptable as well (see Table 183-1).

TULAREMIA (See Chap. 183) Tularemia, similar to plague, ordinarily exists in enzootic cycles but infects humans most commonly after an arthropod bite. The infectious inoculum for *Francisella tularensis* is extremely small, perhaps as few as 50 organisms.[19,20] Because pneumonic tularemia is highly lethal, the intentional dispersal of airborne organisms has the potential to cause devastating outbreaks of disease. Unlike pneumonic plague, however, pulmonary tularemia cannot be spread from person to person.

Clinical Findings. Tularemia can be acquired through several routes and present in several clinical forms. Pulmonary tularemia, which presumably would be the main form seen after intentional airborne spread, lacks cutaneous lesions. Airborne spread could, however, lead to other forms of the disease, such as oculoglandular and gastrointestinal, which in some cases have mucocutaneous findings.

Treatment. A live-attenuated tularemia vaccine has been used in the former Soviet Union. In the United States, the National Institutes of Health and the Department of Defense are funding development of a newer vaccine. Tularemia is a reportable disease and any pulmonary case or cluster of other cases should launch an epidemiologic investigation. In the event of an outbreak of pneumonic tularemia, health authorities should consider community prophylaxis with doxycycline or ciprofloxacin. Streptomycin (or in its absence, gentamicin) treats all forms of tularemia successfully if administered early in the course of the disease. Clinical improvement is evident within 24 to 48 hours, but treatment should be continued for at least 7 to 10 afebrile days. Tetracycline and chloramphenicol are acceptable alternatives but should be given for longer periods than 21 and 14 days, respectively, to reduce the risk of relapse.[20]

TABLE 213-5
Clinical Presentations of Classic Chickenpox and Smallpox

CHICKENPOX	SMALLPOX
• Mild or no prodrome	• Febrile prodrome
• Superficial vesicles	• Deep pustules
• "Dew drops on a rose petal"	• "Pearls of pus"
• Individual lesions evolve rapidly	• Individual lesions evolve gradually
• Lesions with different morphologies	• Lesions with same morphology
• Central predominance	• Acral predominance
• Spares palms and soles	• Involves palms and soles
• Patient is rarely toxic	• Patient is usually toxic or moribund

SMALLPOX (See Chap. 195) After the World Health Organization declared that naturally occurring smallpox was eradicated, laboratories worldwide destroyed their stocks of variola—except for a few facilities that maintained small amounts of virus, putatively for research purposes. With the collapse of the Soviet Union and the dismantling of its military medical research system, there have been concerns that rogue states or terrorist organizations have obtained unmonitored stocks of virus. Any recurrence of smallpox represents a catastrophic medical, public health, and criminal event of extraordinary proportions.

The differential diagnosis of smallpox and varicella is in Table 213-5.

The CDC has an algorithm for the evaluation of suspected smallpox and offers a differential diagnosis. The algorithm, *Evaluating patients for smallpox: acute, generalized vesicular or pustular rash illness protocol* (available at http://www.bt.cdc.gov/agent/smallpox/diagnosis/pdf/spox-poster-full.pdf), identifies three features at the core of a clinical diagnosis of smallpox (Box 213-1).[25]

Dermatologists who serve as bioterrorism resources for their communities or hospitals must become familiar with smallpox vaccination programs. Vaccinia, an orthopoxvirus related to smallpox and to the cowpox originally used in Jenner's inoculations, can produce several cutaneous adverse effects, which require some expertise to diagnose and manage. These conditions are reviewed in detail in Chap. 195.

Category B Agents and Diseases with Possible Cutaneous Manifestations

BRUCELLOSIS (See Chap. 183) Brucellosis is a zoonotic infectious disease that is usually transmitted to humans by direct contact with infected animals or animal products or by ingestion of contaminated dairy products. It can also be transmitted via aerosolized propagules and requires a small inoculum, perhaps 10 to 100 organisms, to cause human disease. Hence, it is regarded as a possible biologic weapon.

Deliberate spread of aerosolized bacteria would cause pulmonary disease, which has a mortality rate, even when untreated, of less than 5 percent. The disease can cause profound fatigue and requires prolonged treatment, hence victims could be incapacitated for months. Subsequent human-to-human transmission will not occur. Cutaneous manifestations of brucellosis are uncommon and non-specific and are discussed in detail in Chap. 183.

MELIOIDOSIS AND GLANDERS (See Chap. 183) As biologic weapons, these organisms would be disseminated in aerosols that cause respiratory outbreaks. Only a small inoculum of either is required to cause illness. The incubation period is roughly 10 to 14 days and the subsequent pulmonary disease has a mortality rate of more than 95 percent untreated or approximately 40 percent when treated with appropriate antibiotics. Pulmonary disease can lead to bacteremia or septicemia, which can produce cutaneous and subcutaneous abscesses (see Chap. 183).[28–30]

The first case of human glanders in the United States in more than 50 years was reported in 2002 in a microbiologist who was inadvertently exposed at an Army Research Laboratory. He developed axillary lymphadenopathy and bacteremic infection with hepatic and splenic abscesses but responded well to prolonged treatment with imipenem and doxycycline.[31]

Category C Bioweapons (See Table 213-3)

Category C is an expanding list of diseases, mostly caused by emerging pathogens that could possibly be engineered for mass dissemination and major public health impact.[9] The number of diseases in Category C continues to expand as new diseases, such as severe acute respiratory syndrome, avian flu (caused by the H5N1 strain of influenza A virus), and Nipah virus infection are recognized for their potential for high morbidity, mortality, and societal disruption.[9]

Most diseases currently in Category C lack specific dermatologic findings.

Box 213-1
Core Features in the Clinical Diagnosis of Suspected Smallpox

- Febrile prodrome occurring 1–4 days before rash onset with fever ≥ 38.3°C (101°F) and at least one of the following: prostration, headache, backache, chills, vomiting, or severe abdominal pain.
- Classic smallpox lesions are deep-seated, firm or hard, round, well-circumscribed vesicles or pustules that are sharply raised and feel like small, round objects embedded under the skin. As they evolve, the lesions may become umbilicated or confluent.
- Lesions in the same stage of development: On any one part of the body (e.g., face or arm), all lesions are in the same stage of development—that is, all are vesicles or all are pustules.

CHEMICAL WEAPONS

Chemical weapons were used on a grand scale during World War I by the Imperial German Army and then by the Allied Forces in response. The morbidity, mortality, and terror associated with these weapons exceeded that of any known conventional weapon.[32,33] Soon after the 1918 Armistice, international treaties limited—then ultimately banned—the use of chemical agents during warfare. Although these prohibitions are regarded as international law, not all nations have signed and ratified the various treaties. Furthermore, the ban on chemical weapons specifies use during declared wars with adversary nations. The treaties do not, however, explicitly forbid the use of chemical weapons against non-combatants or within one's own country.

The Japanese cult, Aum Shinrikyo, used another chemical weapon, the nerve agent sarin, in Tokyo's subways in an act of domestic terrorism. Although no one was killed, this attack underscores the fact that rogue organizations can obtain or develop their own unconventional weapons.[35]

Chemical weapons are divided somewhat loosely into categories based on their effects on human victims: blister agents, nerve agents, blood agents, urticating agents, choking agents, and incapacitating agents. Table 213-6 identifies prototypical members of the major categories and describes mechanistic and clinical features of these agents.

TABLE 213-6
Major Categories of Chemical Weapons and Their Major Effects

Class of Agent	Example of Agent	Physical Form of Weaponized Substance	Mechanism of Action	Route of Exposure	Time to Onset of Signs and Symptoms	Non-Dermatologic Signs and Symptoms	Cutaneous Reactions	Immediate Treatment[a] Includes	Definitive Treatment Includes	Differential Diagnosis
Blood agent	Hydrogen cyanide	Liquid or vapor	Inactivates cytochrome oxidase, thereby preventing cells from using oxygen.	Inhalation, cutaneous, mucosal	Seconds to minutes	Low dose: dizziness, nausea, headache, eye irritation. High dose: loss of consciousness; cessation of respiration.	Often with cherry red skin.	Remove from environment. Remove clothing. Flush skin with copious water. Oxygen.	Oxygen. Amyl nitrite or sodium nitrite, followed by sodium thiosulfate. Respiratory support.	Carbon monoxide poisoning. Hydrogen sulfide (sewer gas) poisoning
Blistering agent	Mustard gas, mustard agent, yperite, sulfur mustard	Liquid or vapor	Alkylating agent (related to medical nitrogen mustard) but precise mechanism in the skin is not known.	Inhalation, cutaneous, mucosal	Hours to days	Red, irritated eyes with conjunctivitis and lid edema. Vomiting. Nasal irritation, cough.	Erythema, pruritus, blistering.	Remove from environment. Remove clothing. Flush skin with copious water or hypochlorite. Irrigate eyes with saline.	No antidote exists. Definitive eye care. Pain relief. Respiratory support. If the blister agent is Lewisite rather than sulfur mustard, use Dimercaprol (British antilewisite).	Exposure to other irritants (e.g., caustics, ammonia, sodium hydroxide)
Nerve agent	Tabun, sarin, VX	Liquid or gas	Inhibits acetyl-cholinesterase, allowing excess acetylcholine to accumulate (which overstimulates muscles, glands, and nerves) and allowing unrestrained parasympathetic (specifically muscarinic) activity.	Inhalation, cutaneous, mucosal	Vapor: seconds to minutes Liquid: minutes to hours	Pinpoint pupils, lacrimation, asthma-like wheezing, fasciculating muscles, perspiration, hypersalivation, diarrhea. Higher doses: seizures, apnea, loss of consciousness.	Perspiration and piloerection.	Remove from environment. Remove clothing. Flush with copious amounts of water or warm soapy water. Atropine and pralidoxime.	Repeated doses of atropine to reduce secretions. Pralidoxime as needed. Consider diazepam to prevent seizures, inc atropine-induced seizures. Respiratory support.	Organophosphate pesticide poisoning
Urticating agent	Phosgene, nettle gas, oxime	Gas	Not known.	Inhalation, cutaneous, mucosal	Seconds to minutes	Burning eyes, rhinorrhea, hoarseness, dyspnea, cough.	Immediate pain and severe burning on skin contact. Soon, urticaria-like edema, followed by blisters on day 2. May cause deep necrosis of skin.	Remove clothing. Flush with copious amounts of water or sodium bicarbonate solution.	Supportive burn care.	Exposure to other irritants (e.g., caustics, ammonia, sodium hydroxide)
Choking agent	Phosgene, carbonyl chloride, carbonic acid dichloride	Gas or liquid that vaporizes easily	Not known. Increases permeability of alveolar capillaries leading to non-cardiogenic pulmonary edema.	Inhalation	Hours	Dyspnea, chest tightness, wheezing, red mucosa; erythema, causes noncardiac pulmonary edema.	None.	Remove from environment. Oxygen. Consider intubation. Flush eyes with water.	Oxygen, respiratory support.	Industrial gas exposure (e.g., ammonia, hydrochloric acid)

[a]Personal protective measures [e.g., chemical hazard suit and protective mask (gas mask)], are usually necessary before one can assist a victim of a chemical weapon attack.

The class with the most severe effects on the skin is that of blister agents.[32,33,35]

Blister agents, notably sulfur mustard (HD), are the most commonly used chemical weapons. HD was first used during World War I in battles around Ypres, Belgium, hence its other name, *yperite*. Because of a mustard- or garlic-like odor, the compound is often called *mustard gas*. Saddam Hussein's Iraqi military forces used HD against the Iranian army (1980–1988) and against Iraqi citizens in Kurdish villages, such as Halabja.

HD is a relatively simple compound; it can be synthesized by combining two moieties, sulfur dichloride and ethylene. It is inexpensive to manufacture, stable in storage, and can be delivered by many means—therefore, it is likely to be the chemical weapon of choice for a terrorist organization.

HD is an amber-colored, viscous liquid that is lipid soluble, thereby passing easily into and through the skin. If HD lands on someone's skin, roughly 80 percent evaporates quickly, 10 percent passes through the skin and enters systemic circulation, and 10 percent remains in the skin. Victims first experience an irritated, gritty feeling in their eyes. This progresses over hours to a chemical conjunctivitis and massive lid edema. Ocular effects can last several weeks and may destroy the cornea or even rupture the globe. Victims also suffer severe nausea and vomiting within several hours of exposure.

The skin starts itching within hours and then develops a diffuse non-specific erythema later on the first day. Blisters begin to appear at 1 to 2 days, starting as small vesicles that coalesce to form large, extensive bullae.

HD penetrates the skin within minutes and there is no antidote. Therefore, for decontamination to be effective, it must be started immediately. Responders must don full protective gear (chemical hazard suit and a protective breathing mask) and remove the victim from the contaminated environment. The victim's clothes must be removed completely and the body washed—flooded—with copious amounts of water. Warm soapy water is better and a hypochlorite solution (one part household bleach to nine parts water) is best. The eyes must be flushed with saline.

Subsequent care is largely supportive and the patient feels better when given nonsteroidal anti-inflammatory drugs to counter inflammation and placed in a cool environment. It is necessary to manage fluids and electrolytes and to remain vigilant for secondary infection. In vivo animal studies suggest that débridement of blisters increase the rate of wound healing, but human studies have not been conducted. Healing is largely a matter of time and leaves persistent zones of hyperpigmentation at the affected areas.[32,33,35–37]

RADIOLOGIC WEAPONS

Terrorist organizations are unlikely to possess true nuclear weapons but may have what is known as a *dirty bomb*. This type of weapon presents a radiation hazard by using conventional explosives, such as dynamite, to scatter radioactive debris or dust, which then contaminates an area. Dirty bombs do not trigger nuclear chain reactions but instead produce low levels of radiation. Accordingly, exposed individuals are unlikely to experience acute radiation injury. The immediate effects of a dirty bomb will most likely be due to the force of the blast, which can harm people and destroy property. The lasting effects of a dirty bomb include contamination of a zone, rendering it uninhabitable until the difficult task of area decontamination is complete.

Individuals exposed to radiation from a dirty bomb must rid themselves of lingering radioactive dust or debris. Ideally, this will be conducted at a designated decontamination station. Victims must remove all clothes and then wash their entire bodies thoroughly with soap and water. The decontamination station should contain, collect, and dispose of the clothes and water in a manner that is safe and appropriate for radioactive waste.

In the event of a suspected attack with a chemical or radiologic weapon, medical personnel must coordinate with public health and law enforcement agencies at the local, state, and federal level.[33,38,39]

SECTION 36

TOPICAL THERAPY

CHAPTER 214

Principles of Topical Therapy

Kendra G. Bergstrom
Bruce E. Strober

Sensible topical drug therapy involves not only the selection of an appropriate agent, but also a thoughtful consideration of the areas of the body affected, the state of the diseased skin, the concentration of the drug, the type of vehicle (e.g., ointment, cream, lotion), the method of application, and a defined duration of use that both maximizes efficacy and minimizes adverse side effects. Behind each of these considerations are basic principles that help guide the practitioner toward a rational plan of therapy.

CUTANEOUS DRUG DELIVERY

The therapeutic efficacy of a topical drug relates to both its inherent potency and the ability of that drug to penetrate the skin.[1] In fact, many potent agents, such as hydrocortisone and fluocinolone acetonide, are quite poorly absorbed after topical application. Conversely, many well-absorbed agents with weak potency have negligible therapeutic use.

◀ **Top:** Twenty-three-year-old patient with generalized psoriasis. **Left:** Before psoralen and ultraviolet A light treatment. **Right:** After treatment. **Bottom:** Crescentic excision of basal cell carcinoma. **Left:** Excision of tissue around the defect is planned in order to place the incision into the nasolabial fold. **Right:** Six months after surgery.

Percutaneous absorption necessitates passage through the stratum corneum, epidermis, papillary dermis, and into the bloodstream. (See Chap. 215 for information on the pharmacokinetics of topical agents.)

In contrast to many orally administered drugs that are nearly completely absorbed within a few hours, topical medicines generally have a poor total absorption and a very slow rate of absorption. For example, less than 2 percent of a topically applied corticosteroid such as hydrocortisone is absorbed after a single application left on the skin for more than 1 day. Furthermore, peak rates of absorption are reached up to 12 to 24 hours after application. Fortunately, low absorption does not necessarily translate into low efficacy. Drugs such as topical corticosteroids are effective because of their inherent potency and can exert clinically significant effects in spite of low absorption. In this light, absorption represents only one of many facets of efficacy.

OTHER FACTORS THAT AFFECT ABSORPTION

Stratum Corneum

The stratum corneum is the rate-limiting barrier to percutaneous drug delivery. This cornified layer is composed of ceramides, free fatty acids, and cholesterol in a 1:1:1 molar ratio. By weight, the stratum corneum consists of 50 percent ceramides (acylceramides being the most abundant), 35 percent cholesterol, and 15 percent free fatty acids. Of course, the stratum corneum thickness and, thus, drug penetration, will vary depending on body site.[2] Table 214-1 lists varying body sites and their relative resistance to percutaneous absorption. An important consideration in topical therapy is that diseased skin may have an altered (increased, decreased, or absent) stratum corneum, thus changing the body site's barrier function. Abraded or eczematized skin presents less of a barrier. Solvents, surfactants, and alcohols can denature the cornified layer and increase penetration; as a result topical medications with these components may enhance absorption.

Occlusion

Occlusion via closed, airtight dressings or greasy ointment bases increases the

PRINCIPLES OF TOPICAL THERAPY AT A GLANCE

- The efficacy of a topically applied drug depends on its inherent potency and on its ability to penetrate skin.
- Some factors that affect penetration include: Concentration of medication, thickness and integrity of the stratum corneum, frequency of application, occlusiveness of the vehicle, and compliance.
- Topical formulations (vehicles) are meant to enhance the beneficial effects of the medication.
- Either the vehicle or its active ingredient(s) may cause local toxicity.
- Topical medications may induce systemic toxicity.

hydration and temperature of the stratum corneum, limits rub-off/wash-off of the drug, and consequently, enhances drug penetration. Occlusion techniques range from application under an airtight dressing such as vinyl gloves or plastic wrap, to occlusion with cotton gloves or socks at night for treatment of hands and feet, to application of a medication already impregnated into an airtight dressing, as seen in flurandrenolide (Cordran) tape. To derive the greatest benefit from occlusion, the patient should hydrate the skin by immersion in water for approximately 5 minutes before the application of a cream or ointment. Clinically, this may correspond to application immediately after bathing and before drying completely. With many drugs, occlusion increases drug delivery by 10 to 100 times the amount of drug delivered when not occluded.[3] This approach can lead to more rapid onset times and increased efficacy when compared with topical application alone. On the other hand, occlusion may also lead to a more rapid appearance of the drug's adverse effects, such as the ability of topical corticosteroids to induce local skin atrophy or suppression of the hypothalamus-pituitary-adrenal axis. Occlusion may promote infection, folliculitis, or miliaria. In the case of topical anesthetics such as lidocaine and prilocaine, occlusion hastens absorption into both the skin and the bloodstream, which has led in rare cases to cardiac complications from lidocaine toxicity or methemoglobinemia from prilocaine toxicity.

Frequency of Application

The frequency of drug application likely has little effect on increasing a topical drug's overall efficacy.[4,5] One daily application is enough for most topical glucocorticoids, for example, but the non-specific emollient or protective effect of creams and ointments are likely enhanced by more frequent applications. Regardless, increasing the contact time for a topical drug augments its total absorption.

Quantity of Application

The quantity of the drug applied likely has a negligible effect on drug absorption. Obviously enough drug must be dispensed and spread to cover the affected areas. Further, the quantity of drug applied might affect patient adherence to the prescribed regimen. For example, too much applied drug might negatively alter the subjective experience of having a medication on the skin, i.e., the drug may feel "wrong" (greasy, caked, chalky, etc.) or is cosmetically unattractive (shiny, white color). Regardless, the amount prescribed must be adequate to treat the affected body surface area for the necessary length of time. In this regard, patient education is critical to prevent wasteful overuse or ineffective underuse of the medication. The amounts of topical medications to dispense, based on the estimated body surface area, frequency of application, and duration of therapy, are presented in Table 214-2. For topical medications like sunscreens that are used over large areas, underapplication is a problem for most patients. However, for smaller areas, patients may apply a large amount of an ointment, for example, leading to complaints of greasiness or rubbing off on clothing, which can be minimized by using an appropriate amount.

Compliance

Topical medication compliance is a critical although often overlooked aspect of medication efficacy. Generally, adherence to a treatment regimen is associated with female gender, employment, being married, and low prescription costs. Lower adherence is seen for patients with extensive disease, and paradoxically, disease on the face.[6] One 8-week survey using electronic monitoring showed that adherence to treatment for a twice-daily topical prescription decreased from 84 percent the first week to 51 percent during the eighth week, with topical non-compliance being especially notable on weekends.[7] Furthermore, compliance is negatively affected by depression, which is common in people with chronic skin conditions and found in up to 20 percent of patients with psoriasis.[8]

Miscellaneous Factors

Vigorous rubbing or massaging of the drug into the skin not only increases the surface area of skin covered, but also increases blood supply to the area locally, augmenting systemic absorption. It may cause a local exfoliative effect that will also enhance penetration. The presence of hair follicles on a particular body site also enhances drug delivery, with the scalp and beard areas presenting less of a barrier when compared with the relatively hairless body sites. Although having a thinner stratum corneum, the skin of older individuals is poorly hydrated, with fewer hair follicles and therefore may impede drug delivery.

Reducing the particle size of the active ingredient increases its surface area–volume ratio, allowing for a greater solubility of the drug in its vehicle. This forms the basis for the increased absorption of certain micronized drugs.[9]

TABLE 214-2
Suggested Amounts of Topical Medications to Dispense—Cream or Ointment

Area Treated	Estimated % Body Surface Area	Single Application (g)	Twice a Day for 1 Week (g)	Thrice a Day for 1 Week (g)

From New York University's Dermatologic Formulary—Skin and Cancer Unit.

CLASSIFICATION AND CLINICAL APPLICATION OF TOPICAL FORMULATIONS

The vehicle is the inactive part of a topical preparation that brings a drug into contact with the skin. Before the mid-1970s pharmaceutical companies performed limited testing of the impact of the vehicle on the potency of a given formulation. The lack of a scientific analysis of the vehicle led to the marketing of topical drugs that, while having different concentrations of the same active ingredient, nevertheless exhibited similar bioavailability and potency. For example, older preparations of triamcinolone acetonide showed no real differences in potency among the 0.025 percent, 0.1 percent, and 0.5 percent concentrations. By contrast, modern drug development attempts to maximize drug bioavailability by optimizing vehicle formulation. Additionally, during the current drug development process, dose-response studies determine the maximal effective concentration within a given vehicle, above which any further increase in concentration serves no therapeutic benefit.

The vehicle of a topical formulation often has beneficial non-specific effects by possessing cooling, protective, emollient, occlusive, or astringent properties. Rational topical therapy matches an appropriate vehicle that contains an effective concentration of the drug. The vehicle functions optimally when it is stable both chemically and physically and does not inactivate the drug. The vehicle also should be nonirritating, nonallergenic, cosmetically acceptable, and easy to use. Additionally, the vehicle must release the drug into the pharmacologically important compartment of the skin. Finally, the patient must accept using the vehicle or else compliance will be poor. For example, although ointments are often pharmacodynamically more effective than creams, patients generally prefer creams to ointments, and thus, it is no surprise that more prescriptions are written for cream-based formulations. Table 214-3 lists many commonly used ingredients in topical preparations. Many of these compounds may serve more than one function in a particular formulation.

Powders

Powders absorb moisture and decrease friction. Because they adhere poorly to the skin, their use is mainly limited to cosmetic and hygienic purposes. Generally, powders are used in the intertriginous areas and on the feet. Adverse effects of powders include caking (especially if used on weeping skin), crusting, irritation, and granuloma formation. Further, powders may be inhaled by the user. Most powders contain zinc oxide for its antiseptic and covering properties, talc (primarily composed of magnesium silicate) for its lubricating and drying properties, and a stearate for improved adherence to the skin. Calamine is a popular skin-colored powder composed of 98 percent zinc oxide and 1 percent ferric oxide and acts as an astringent to relieve pruritus. Other drugs formulated as powders include some over-the-counter antifungals.[9]

Poultices

A poultice, also referred to as a *cataplasm*, is a wet solid mass of particles, sometimes heated, that is applied to diseased skin. Historically, poultices contained meal, herbs, plants, and seeds. The modern poultice often consists of porous beads of dextranomer. Poultices are used as wound cleansers and absorptive agents in exudative lesions such as decubiti and leg ulcers.[9]

Ointments

Ointments are semisolid preparations that spread easily. They can be protective, hydrating, and lubricating. Ointment bases used in dermatology can be classified into five categories: hydrocarbon bases, absorption bases, emulsions of water-in-oil, emulsions of oil-in-water, and water-soluble bases. Dermatologists commonly refer to the hydrocarbon bases and absorption bases as *ointments* and the water-in-oil/oil-in-water emulsion bases as *creams*. In pharmaceutical terms, all of these preparations are ointments.

HYDROCARBON BASES Also called *oleaginous bases*, hydrocarbon bases are often referred to as *emollients* because they prevent the evaporation of moisture from the skin and are composed of a

TABLE 214–3
Vehicle Ingredients Commonly Used in Topical Preparations

Emulsifying agents	Solvents
Cholesterol	Alcohol
Disodium monooleamidosulfosuccinate	Diisopropyl adipate
Emulsifying wax	Glycerin
Polyoxyl 40 stearate	1,2,6-Hexanetriol
Polysorbates	Isopropyl myristate
Sodium laureth sulfate	Propylene carbonate
Sodium lauryl sulfate	Propylene glycol
Auxiliary emulsifying agents/emulsion stabilizers	Water
Carbomer	Thickening agents
Catearyl alcohol	Beeswax
Cetyl alcohol	Carbomer
Glyceryl monostearate	Petrolatum
Lanolin and lanolin derivatives	Polyethylene
Polyethylene glycol	Xanthan gum
Stearyl alcohol	Emollients
Stabilizers	Caprylic/capric triglycerides
Benzyl alcohol	Cetyl alcohol
Butylated hydroxyanisole	Glycerin
Butylated hydroxytoluene	Isopropyl myristate
Chlorocresol	Isopropyl palmitate
Citric acid	Lanolin and lanolin derivatives
Edetate disodium	Mineral oil
Glycerin	Petrolatum
Parabens	Squalene
Propyl gallate	Stearic acid
Propylene glycol	Stearyl alcohol
Sodium bisulfite	Humectants
Sorbic acid/potassium sorbate	Glycerin
	Propylene glycol
	Sorbitol solution

mixture of hydrocarbons of varying molecular weights, with petrolatum being the most commonly used (white petrolatum, except for being bleached, is identical to yellow petrolatum). They are greasy and can stain clothing. The silicon ointments are composed of alternating oxygen and silicon atoms bonded to organic groups, such as phenyl or methyl, and are excellent skin protectants. They can be used for diaper rash, incontinence, bedsores, and colostomy sites. Hydrocarbon bases are generally stable and do not contain preservatives. They cannot absorb aqueous solutions, and thus are not used for water-soluble drugs.[9]

ABSORPTION BASES Absorption bases contain hydrophilic substances that allow for the absorption of water-soluble drugs. The hydrophilic (polar) compounds may include lanolin and its derivatives, cholesterol and its derivatives, and the partial esters of polyhydric alcohols such as sorbitan monostearate. These ointments are lubricating and hydrophilic, and they can form emulsions. They function well as emollients and protectants. They are greasy to apply but are easier to remove than the hydrocarbon bases. They do not contain water. Examples include anhydrous lanolin and hydrophilic petrolatum.[9]

WATER-IN-OIL EMULSIONS (CREAMS) Emulsions are two-phase systems involving one or more immiscible liquids dispersed in another, with the assistance of an emulsifying agent. A water-in-oil emulsion, by definition, contains less than 25 percent water, with oil being the dispersion medium. The two phases may separate unless shaken. The emulsifier (or surfactant) is soluble in both phases and surrounds the dispersed drops to prevent their coalescence. Examples of surfactants used include sodium lauryl sulfate, the quaternary ammonium compounds, Spans (sorbitan fatty acid esters), and Tweens (polyoxyethylene sorbitan fatty acid esters). Preservatives are frequently added to increase the emulsion's shelf life. Water-in-oil emulsions are less greasy, spread easily on the skin, and provide a protective film of oil that remains on the skin as an emollient, while the slow evaporation of the water phase provides a cooling effect.[9]

OIL-IN-WATER EMULSIONS An oil-in-water emulsion contains greater than 31 percent water. In fact, the aqueous phase may comprise up to 80 percent of the formulation. This type of formulation is the one most commonly chosen to deliver a dermatologic drug. Clinically, oil-in-water emulsions spread very easily, are water washable and less greasy, and are easily removed from the skin and clothing. Invariably, they contain preservatives, such as the parabens, to inhibit the growth of molds. Additionally, oil-in-water emulsions contain a humectant (an agent that draws moisture into the skin), such as glycerin, propylene glycol, or polyethylene glycol (PEG), to prevent the cream from drying out. The oil phase may contain either cetyl or stearyl alcohol (paraffin alcohols) to impart a stability and velvety smooth feel upon application to the skin. After application, the aqueous phase evaporates, leaving behind both a small hydrating layer of oil and a concentrated deposit of the drug.[9]

WATER-SOLUBLE BASES Water-soluble bases consist either primarily or completely of various PEGs. Depending on their molecular weight, PEGs are either liquid (for example, PEG 400) or solid (PEG 4000). These formulations are water soluble, will not decompose, and will not support the growth of mold, and therefore require no preservative additives. They are much less occlusive than water-in-oil emulsions, nonstaining, greaseless, and easily washed off of the skin. Without water, this ointment poorly delivers its co-formulated drug. Therefore, it will be useful in scenarios where the practitioner desires a high surface concentration and low percutaneous absorption of the drug. For example, topical antifungal drugs and topical antibiotics (e.g., mupirocin) are formulated in this type of base.

Gels are made from water-soluble bases by formulating water, propylene glycol, and/or PEGs with a cellulose derivative or carbopol. A gel consists of organic macromolecules uniformly distributed in a lattice throughout the liquid. After application, the aqueous or alcoholic component evaporates, and the drug is deposited in a concentrated form. This provides a faster release of the drug independent of its water solubility. Gels are popular because of their clarity and ease of both application and removal. They are also easy to use on the hair-bearing body sites. Nevertheless, they lack any protective or emollient properties. If they contain high concentrations of alcohol or propylene glycol, they tend to be drying or cause stinging. Gels require preservatives.[9] Newer gel formulations may contain the humectant glycerin, the emollient dimethicone, or the viscoelastic polysaccharide hyaluronic acid, which can mitigate some of the associated irritation. Non-aqueous gels, with bases such as glycerol, may be used for poorly solubilized therapeutics such as 5-aminolevulonic acid.[10]

Microspheres, or microsponges, are formulated in an aqueous gel. Medication, in this case tretinoin, is combined into porous beads 10 to 25 μm in diameter. The beads are made up of methyl methacrylate and glycol dimethacrylate.

Pastes

Pastes are simply the incorporation of high concentrations of powders (up to 50 percent) into an ointment such as a hydrocarbon base or a water-in-oil emulsion. The powder must be insoluble in the ointment. Invariably, they are "stiffer" than the original ointment. The powders commonly used are zinc oxide, starch, calcium carbonate, and talc. Pastes function to localize the effect of a drug that may be staining or irritating (i.e., anthralin). They also function as impermeable barriers that serve as protectants or sunblocks. Pastes are less greasy than ointments, more drying, and less occlusive.[9]

Liquids

Liquids can be subdivided into solutions, suspensions, and emulsions (discussed in Ointments).

SOLUTIONS A solution involves the dissolution of two or more substances into homogenous clarity. The liquid vehicle may be aqueous, hydroalcoholic, or non-aqueous (alcohol, oils, or propylene glycol). An example of an aqueous solution is aluminum acetate or Burow's solution. A hydroalcoholic solution with a concentration of alcohol of approximately 50 percent is called a *tincture*. A collodion is a non-aqueous solution of pyroxylin in a mixture with ether and ethanol, and is applied to the skin with a soft brush. Flexible collodions have added castor oil and camphor and are used, for example, to deliver 10 percent salicylic acid as a keratolytic agent and cantharidin for the treatment of warts. Liniments are non-aqueous solutions of drugs in oil or alcoholic solutions of soap. The base of oil or soap facilitates application to the skin with rubbing or massage. Liniments can be used as counterirritants, astringents, antipruritics, emollients, and analgesics.[9]

SUSPENSIONS (LOTIONS) A suspension, or lotion, is a two-phase system consisting of a finely divided, insoluble drug dispersed into a liquid in a concentration of up to 20 percent. Non-uniform dosing can result if the suspended particles coalesce and separate out of a homogeneous mixture, therefore shaking of the lotion before application may be required. Examples include calamine lotion, steroid lotions, and emollients containing urea or lactic acid. The applied lotion leaves the skin feeling cooler via evaporation of the aqueous component. Lotions are easier to apply and allow for uniform coating of the affected area, and are often the favorite preparation in treating children. Lotions are more drying than ointments, and preparations with alcohol tend to sting eczematized or abraded skin.[9]

SHAKE LOTIONS Shake lotions are lotions to which a powder is added to increase the surface area of evaporation. As a result of the increased evaporation, the application of shake lotions effectively dries and cools wet and weeping skin. Generally, shake lotions consist of zinc oxide, talc, calamine, glycerol, alcohol, and water, to which specific drugs and stabilizers may be added. Shake lotions tend to sediment, and derive their name from the need to shake the preparation before each use to obtain a homogeneous suspension. In addition, after water has evaporated from the lotion, the powder component may clump together and become abrasive. Therefore, patients should be instructed to remove the residual particles before the reapplication of shake lotions.[9]

Aerosols

Topical aerosols may be used to deliver drugs formulated as solutions, suspensions, emulsions, powders, and semisolids. Aerosols involve formulating the drug in a solution within a pure propellant. Usually, the propellant is a blend of nonpolar hydrocarbons. When applied to abraded or eczematized skin, aerosols lack the irritation of other formulations, especially when the quality of the skin makes direct application painful or difficult. Furthermore, aerosols dispense a drug as a thin layer with minimal waste, and the unused portion cannot be contaminated. Aerosol foams, a relatively new vehicle for drug delivery, are commonly used to deliver corticosteroids such as betamethasone valerate and clobetasol propionate. The foam contains the drug within an emulsion formulated with a foaming agent (a surfactant), a solvent system (such as water and ethanol), and a propellant. On application, a foam lattice forms transiently until it is broken by both the heat of the skin and the heat of rubbing the foam onto the skin. Foams that are alcohol based leave very little residue within seconds of their application. Furthermore, a given corticosteroid formulated in a foam vehicle demonstrates comparable potency when compared with the same corticosteroid in other vehicles.[1,11] Although aerosols allow for the ease of application (especially to hair-bearing areas) and high patient satisfaction, they suffer from the disadvantages of being expensive and potentially ecologically damaging.[9]

Stabilizers

Stabilizers are non-therapeutic ingredients and include the preservatives, antioxidants, and chelating agents. Preservatives protect the formulation from microbial growth. The ideal preservative is effective at a low concentration against a broad spectrum of organisms, nonsensitizing, odor free, color free, stable, and inexpensive. Unfortunately, the ideal preservative does not exist. The parabens are the most frequently added preservatives, and are active against molds, fungi, and yeasts, but less effective against bacteria. Alternative agents include the halogenated phenols, benzoic acid, sodium benzoate, formaldehyde, the formaldehyde-releasing agents, and previously, thimerosal. Most commonly used preservatives may act as contact sensitizers.

Antioxidants or preservatives prevent the drug or vehicle from degrading via oxidation. Examples include butylated hydroxyanisole and butylated hydroxytoluene, used in oils and fats. Ascorbic acid, sulfites, and sulfur-containing amino acids are used in water-soluble phases. Chelating agents, such as sodium EDTA and citric acid, work synergistically with antioxidants by complexing heavy metals in aqueous phases.

Thickening Agents

Thickening agents increase the viscosity of products or suspend ingredients in a formulation. Examples include beeswax and carbomers. In addition to functioning as an ointment vehicle, petrolatum may be added to an emulsion to increase its viscosity. As in this example, an ingredient may have a therapeutic effect as well as acting as part of a vehicle.

TOXICITY OF TOPICAL DRUGS

Local Effects

Either the vehicle or its active ingredients may cause local toxicity to the applied site. Local adverse effects are usually minor and reversible. Major cutaneous side effects include irritation, allergenicity, atrophy, comedogenicity, formation of telangiectases, pruritus, stinging, and pain. The mechanism of toxicity may be as simple as the desiccation of the stratum corneum (the removal of sebum and oils by the preparation's emulsifiers, for example), or involve a more complex effect on either the cells of the epidermis or dermis and the structures these cells comprise (i.e., epidermis, adnexae). Local damage may occur either directly at, or within close proximity to, the treated site. Further, irritation and damage may appear even after a drug has been discontinued. Often the therapeutic effects of the active ingredient mask or immediately treat the toxic effects of the formulation so that acutely toxic effects are transient.[12] For example, an allergic contact dermatitis to a preservative in a topical steroid may be masked by the effects of the steroid itself.

Irritation is driven less by drug penetration and more by drug concentration. Thus, lowering the concentration of an irritating drug may lower the risk of side effects. However, a change in formulation may reduce the preparation's efficacy. Nevertheless, often using a less concentrated preparation over a greater period of time is as therapeutically efficacious while minimizing adverse effects; for example, the use of benzoyl peroxide 2 percent to 5 percent preparations in contrast to 10 percent preparations.[12] In some instances, though, skin irritancy might be central to drug efficacy. For example, although not conclusively shown, the power of immunomodulating agents such as imiquimod might rely on an increased innate (inflammatory or irritant) immune response.

In contrast to local irritation, contact allergy development depends on local penetration. Allergy, of course, is driven by antigen recognition and presentation, and thus, percutaneous absorption of the drug must be at a level that guarantees interaction with the immune effector cells of the skin. Therefore, the contact allergenicity of a

drug relates most significantly to percutaneous absorption.

Systemic Effects

One should be aware of the potential systemic toxicities of topical drugs. Although generally safer than the other routes of administration, topical application can result in systemic toxicities ranging from end-organ toxicity (central nervous system, cardiac, renal, etc.), teratogenicity, and carcinogenicity to drug interactions. These outcomes may relate to the drug itself, its metabolites, or even a component of the vehicle.

The kinetics of topically applied drugs differ significantly from those administered by other routes. One important consideration is the lack of hepatic first-pass metabolism of a topical drug. This is especially relevant to drugs such as salicylic acid that are relatively innocuous when given enterally, but may manifest central nervous system toxicity when applied topically. Additionally, acting as a reservoir, the stratum corneum may store large amounts of a topical drug, and a subsequently long diffusion period of many days may ensue, delivering a steady supply of drug to the systemic circulation.

Percutaneous toxicity directly relates to percutaneous absorption. Therefore, factors that modulate absorption also influence toxicity: the concentration of the drug, its vehicle, the use of occlusion, the body site and area treated, frequency of use, the duration of therapy, and the nature of the diseased skin. For example, 6 percent salicylic acid in Eucerin used for 11 days in the treatment of psoriasis has been shown to result in epistaxis and deafness, while the same concentration of salicylic acid in hydrophilic cream under occlusion for 4 days for the treatment of dermatitis (involving the same amount of body surface area) may result in hallucination.[12] Similar to their effect on systemically administered drugs, renal and hepatic diseases, by influencing drug clearance, also contribute to an increased potential for drug toxicity.

Young children have a greater surface area–volume ratio, and thus are at greater risk of percutaneous toxicity than adults. This phenomenon necessitates alternative drugs, formulations, and dosing schedules for children with widespread cutaneous disease. Patients with acute flares of cutaneous illness (for example, psoriasis or atopic dermatitis) may require the treatment of a larger body surface area in a relatively abbreviated period of time. These patients may also increase their dose and frequency of application during such flares. Coupled with the likely increased percutaneous absorption of the diseased skin, these scenarios exponentially increase the possibility of systemic toxicity, and patient education is vital to prevent adverse outcomes.[9] To reduce the risk of toxicity from topical drugs and to increase treatment efficacy, many practitioners will rationally advocate systemic approaches (i.e., methotrexate, cyclosporine, injectable or infusable biologics, or ultraviolet radiotherapy) to patients whose disease involves an extensive body surface area.

In rare instances, anaphylactic shock can be precipitated by topical drug application. For example, when applied to diseased or abraded skin, bacitracin ointment can induce an immediate-type (type I) hypersensitivity reaction in susceptible individuals. Such reactions might be represented by a local and then subsequently generalized pruritus leading to cardiopulmonary arrest.[13] Nonimmunologic acute toxicity results from substances such as pesticides and chemical warfare agents that rapidly diffuse through the skin and reach target organs.

Transdermal drug delivery, in contrast to topical drug delivery, uses topical application of therapeutic drug as a delivery system for systemic therapy. Transdermal patches have been approved by the U.S. Food and Drug Administration since 1981 (scopolamine being the first) for the delivery of 13 different medications, with more seeking approval. The most commonly used patches are for nitroglycerin and fentanyl (Duragesic). Advantages of this approach include controlled release, a steady blood-level profile with zero-order kinetics, lack of a plasma peak, and, in some cases, improved patient compliance. These patches remain on the skin for 12 hours to 1 week. A patch consists of a plastic backing, a reservoir of medication, either a rate-controlling membrane or a polymer matrix system for controlled diffusion, followed by an adhesive facing the skin. The most common adhesives used are acrylates, silicones, and polyisobutylenes. These patches have been tested and are approved for use on the thighs, buttocks, lower abdomen, upper arms, and chest; application to other sites can lead to either sub- or supratherapeutic blood levels. Adverse effects of patches include local irritation and allergic contact dermatitis to either an adhesive or to the drug itself and may necessitate discontinuation.

Topical therapies are a mainstay of treatment for the dermatologist. An understanding of the interactions between a drug's concentration, penetration, availability, and treatment of diseased skin allows physicians to maximize both efficacy and tolerability of topical therapy. An understanding of local and systemic toxicities allows selection of appropriate, safe therapy for patients and minimizes unwanted effects. Appropriate selection of topical agents, and patient education on proper use, can optimize therapeutic outcomes.

CHAPTER 215

Pharmacokinetics and Topical Applications of Drugs

Hans Schaefer
Thomas E. Redelmeier
Gerhard J. Nohynek
Jürgen Lademann

Pharmacokinetics related to topical applications of drugs describes the time-dependent drug concentration following the application of the drug to the skin surface, its subsequent passage through the skin barrier into the underlying skin layers, and its distribution into the systemic circulation. The subject continues to hold the attention of research scientists and clinicians alike because of its relevance to dermatologic therapy and the possibility of topical application of current systemic medication that cannot be administered orally, such as peptides or proteins. However, this is an inherently complex subject, despite the advent of new insights into the principal factors that govern diffusion of a drug into and across the skin.

The major difficulty in developing an accurate description of the percutaneous absorption of a drug is related to the size of the compartments. A topical application of a cream or ointment is generally spread to a thickness of not greater than 10 μm. The thickness of the stratum corneum is also approximately 10 μm, whereas the viable epidermis, dermis, and, to a greater extent, the systemic compartment, represent a large sink in which absorbed drugs undergo dilution to levels that often remain undetectable to all but the most sensitive techniques. The determination of the time-dependent changes in the concentration of a drug in individual compartments is technically challenging. After topical application of a drug formulation, these parameters can affect this process:

1. Formulations may undergo drastic changes in composition and structure;
2. The drug or its formulation may affect the skin barrier, resulting in time-dependent changes of the barrier function;
3. The skin barrier may be affected by the type and progression of a disease;
4. There are significant regional variations in the barrier properties of the skin;
5. Viable skin tissues themselves may respond to a topical application of a drug formulation resulting in enhancement or retardation of percutaneous absorption;
6. Skin has a significant metabolic capacity; often, the resulting systemic exposure may be not only to the parent drug, but also to pharmacologically more or less active metabolite(s).

DIFFUSION

Laws of Diffusion

Compounds applied topically to the skin surface migrate along concentration gradients according to well-described laws governing diffusion of solutes in solutions and/or their diffusion across membranes. For a detailed discussion of relevant equations, readers are referred to several comprehensive reviews.[1–4]

Fick's Laws

Diffusion of uncharged compounds across a membrane or any homogenous barrier is described by Fick's first and second laws. The first law states that the steady state flux of a compound (J = moles/cm per second) per unit path length (δ, cm) is proportional to the concentration gradient (ΔC) and the diffusion coefficient (D, cm^2/s).

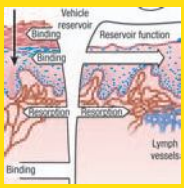
$$J = -D\,(\Delta C/\Delta\delta)$$

The negative sign indicates that the net flux is in the direction of the lower concentration. This equation applies to diffusion-mediated processes in isotropic solutions under steady-state conditions. Fick's second law predicts the flux of compounds under non–steady-state conditions. It is worthwhile to point out that diffusion is a very effective transport mechanism over very short distances but not over long ones. The relationship between the time (Δt) it takes for a molecule to migrate along a path length (x) and its diffusion coefficient is governed by the following equation:

$$\Delta t = x^2/2D$$

For example, the diffusion coefficient for water in an aqueous solution is: 2.5×10^{-5} cm^2/s, suggesting that a water molecule would migrate over a 10-μm path (the equivalent of the width of the stratum corneum) in 0.4 milliseconds. However, because diffusion depends upon the square of the distance, longer distances are not efficiently covered; a 100-μm path would take 40 milliseconds.

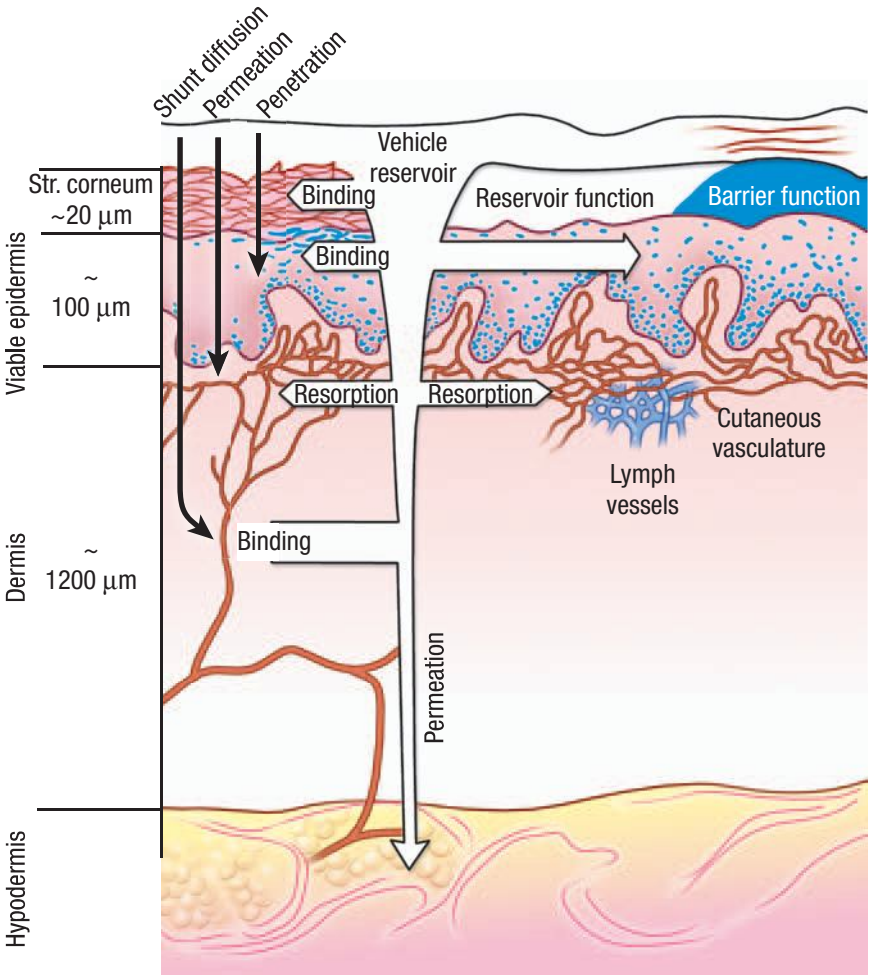
PHARMACOKINETICS AT A GLANCE



- Compounds applied topically to the skin surface migrate along concentration gradients.
- The drug or its formulation may affect the skin barrier, resulting in time-dependent changes of the barrier function.
- There are significant regional variations in the barrier properties of the skin.
- Formulations differ in their physicochemical properties—this influences the kinetics of release and/or absorption and the onset, duration, and extent of a biologic response.
- The primary compartment that limits the percutaneous absorption of compounds is the stratum corneum.
- Diffusion within the viable tissue, as well as metabolism and resorption, also influence the bioavailability of compounds in specific skin compartments.
- Metabolic activity is a primary consideration in the design of prodrugs and may influence the bioavailability of drugs delivered via dermatologic or transdermal formulations.

THREE-COMPARTMENT MODEL

Although pharmacokinetic analysis of topical preparations may require the description of a relatively large number of compartments, this discussion is confined to the three outlined in Fig. 215-1: the skin surface, the stratum corneum, and the viable tissue. The formulation itself forms a reservoir, from which the compound must be released; in order to undergo percutaneous absorption, the compound then must penetrate the stratum corneum, diffuse into and through the viable epidermis into the dermis,



▲ **FIGURE 215-1** Diagrammatic representation of three compartments of the skin: Surface, stratum (Str.) corneum, and viable tissues. After surface applications, evaporation and structural/compositional alterations in the applied formulation may play an important role in determining the bioavailability of drugs. The stratum corneum, the outermost layer, plays the most significant role in determining the diffusion of compounds into the body. After absorption, compounds may bind or diffuse within the viable tissues, or become resorbed by the cutaneous vasculature.

and, finally, gain access to the systemic compartment through the vascular system. In addition, the substance may diffuse through the dermal and hypodermal layers to reach underlying tissues. As summarized in Table 215-1, within each compartment, the compound may diffuse down along its concentration gradient, bind to specific components, or be metabolized. The size or characteristics of each compartment may alter with time, and the factors determining diffusion within each compartment may be affected by disease state as well as the nature or the pharmacologic/biologic activity of the drug or its excipients.

The Skin Surface

SURFACE APPLICATIONS OF FORMULATIONS Formulations differ in their physicochemical properties, and, as discussed in Formulations, this influences the kinetics of release and/or absorption. However, the principal consideration is that topically applied drug products represent a physically small compartment, which limits the amount of compound that can be applied to the skin surface. When a patient applies a dermatologic preparation, the layer of a formulation covering the skin is very thin (approximately 0.5 to 2.0 mg/cm^2). Thicker layers are felt as "unpleasant" and are consciously or subconsciously rubbed off or spread to larger surfaces. This restricts the amount of an active compound that can effectively come in contact with the skin surface to approximately 5 to 20 µg/cm^2 for a 1 percent (wt/wt) topical formulation.

However, even after being rubbed in, formulations do not remain homogeneous over the time course of penetration. For example, topical applications containing water, alcohol, or similar solvents undergo rapid evaporation.[5] This phenomenon is readily recognized by patients as a cooling sensation. The evaporation results in rapidly increasing concentrations of nonvolatile substances on the skin surface, which may result in the formation of supersaturated "solutions" or, alternatively, precipitation of active ingredients. Formulations may also mix with skin-surface lipids or undergo time-dependent changes in their composition as excipients and drugs undergo absorption. Altogether, these considerations suggest that dramatic changes in the composition and structure of formulations may occur following surface application, all of which may determine the subsequent bioavailability of active ingredients.

RESERVOIR The reservoir function was first described by Vickers,[6] who observed that simple occlusion leads to the renewed onset of a glucocorticoid-mediated vasoconstriction several hours after it had declined. He interpreted this effect as renewed liberation of the glucocorticoid from a "reservoir" stored in the upper skin layers.

We define as reservoir the amount of an active ingredient that is still in contact with the nonvolatile constituents of its formulation after the latter had been massaged into the skin surface. The compound has not yet penetrated, but it cannot be removed by simple rubbing or contact with clothing or other tissues. The reservoir thus adheres to the skin surface and resides in the wrinkles and the upper layers of the stratum corneum. Reservoirs on eczematous skin may become even more prominent because of the scaliness of the skin. Recently, we discovered that the upper volume of the follicular channels serves also as a reservoir, which may result in a relative increase in absorption through appendages. In vivo laser scanning microscopy measurements found that the hair follicles represent an efficient reservoir for topically applied formulations, which can be compared with the reservoir of the stratum corneum on several body sites.[7,8] This phenomenon may be increased in formulations that contain particles or precipitates, given the evidence that appropriately sized particles can rapidly penetrate along the shafts of hair follicles to a depth of up to 100 to 500 µm.[9–12]

The optimum size of the particles for penetration into hair follicles is between 300 and 600 nm, which corresponds to

TABLE 215-1
Compartments Encountered by Substances Undergoing Percutaneous Absorption: General Relevance of Processes to Bioavailability

Compartment	Processes	General Relevance to Bioavailability

the cuticular structure of the hairs.[13,14] It was assumed that the rigid hair shaft acts as a geared pump, because this effect could only be observed in the case of moving hairs.[14] The follicular reservoir may result in a relative increase in the absorption of topically applied substances.

No evidence has been found that topically applied substances penetrate efficiently into the sweat glands. This may be due to sweat outflow or other, unknown reasons.

FORMULATIONS Formulations can be differentiated on the basis of whether they are designed to remain on the skin surface (sunscreen products and cosmetics), to be delivered to compartments in the skin (topical formulations), or to migrate across the skin into the central compartment (transdermal formulations).

Formulations may affect the kinetics and the degree of percutaneous absorption and, subsequently, the onset, duration, and extent of a biologic response. In the context of percutaneous absorption, there are several different parameters that should be considered when selecting a formulation[1,15]: the thermodynamic activity of the active ingredient[16]; the amount of compound that can be incorporated into the formulation[17]; the stability of the formulation on the skin surface (e.g., emulsions may break easily)[18]; the partition coefficient of the active ingredient between the vehicle and the stratum corneum[19]; and the enhancer activity.

In general, percutaneous absorption is proportional to the thermodynamic activity of the compound. Thus, the greatest flux is observed at the active ingredient's maximum solubility in a vehicle. Vehicles that are very good solvents should be avoided because they may retain the active ingredient on the skin surface.

LIPOSOMES AS TRANSDERMAL DELIVERY SYSTEMS Liposomes are microscopic spheres comprising a bilayer that encloses an inner aqueous core. A wide variety of cosmetics contain liposomes. Liposome-based formulations have proved to be safe, cosmetically attractive, and well accepted. There is considerable evidence that, at least for some preparations, application of liposomes is mildly occlusive and improves the hydration level of the stratum corneum. Interest in the use of liposomes to enhance the delivery of drugs across the skin has been spurred by several observations in animal models: liposome formulations were believed to enhance the penetration of compounds across the skin or to optimize the retention of bioactive compounds in target tissues.[20] However, these early studies, which relied largely on animal models, were followed by relatively few in vivo studies for humans[17] conducted under standard conditions.

There is good evidence that particles can penetrate along the hair shaft and this route may be appropriate for delivery of bioactive compounds into sebaceous glands or hair follicles.[7,8]

Rigid liposomes penetrate better into the hair follicles than flexible liposomes, which supports the assumption that the moving hairs act as a geared pump.[21]

The Skin Barrier (See Chap. 45)

The primary compartment that limits the percutaneous absorption of compounds is the stratum corneum. This thin (10 to 20 μm) layer effectively surrounds the body and represents a highly differentiated structure that determines the diffusion of compounds across the skin. The physical description of the stratum corneum is well documented,[22] and it can be accurately described as "bricks" of bundled, water-insoluble proteins, embedded in a "mortar" of intercellular lipid.

The stratum corneum is a highly organized, differentiated structure. To participate fully in forming an effective barrier to diffusion, the biogenesis of the corneocytes as well as the synthesis and processing of the intercellular lipid must proceed in an orderly manner. Disruption in the kinetics of skin barrier formation by accelerating the division of the keratinocytes in the underlying layers will lead to a disruption in the barrier properties of the skin.[23] Thus, the concept of dead or dying skin forming a passive barrier to diffusion is now replaced by a model of the stratum corneum as a highly differentiated structure with unique properties that are particularly suited for its role in forming the skin barrier (see Chap. 45).[24]

CORNEOCYTES

INTERCELLULAR LIPID

APPENDAGES (See Chap. 84) A variety of appendages penetrate the stratum corneum and epidermis, facilitating thermal control and providing a protective covering. Appendages are potential sites of discontinuity in the integrity of the skin barrier. The density of the hair follicles varies on different body sites. Hair follicles represent a reservoir that may store topically applied substances. A detailed analysis of the reservoir of the hair follicles showed that the highest reservoir is on the scalp, followed by the forehead and the calf.[29] On the forehead, there are a high number of small follicles, while the calf contains fewer but larger hair follicles. These reservoirs are comparable to the reservoir of the stratum corneum on these body sites.

The percentage of the hair follicles on the total skin surface varies between 0.2 percent and 1.3 percent, depending on the body site.[29] Differences in the follicular penetration were observed in different ethnic groups.[30] Hair follicles appear to present an important pathway for percutaneous absorption in non-diseased skin.[11,12] This can be explained by the fact that only the upper wall of the follicular apparatus (the acroinfundibulum) is protected by a coherent stratum corneum, whereas in the lower part (infrainfundibulum), the corneocytes appear undifferentiated, and protection is incomplete, if not absent. Even solid particles may enter deep into the follicular orifice,[9,10,22] a phenomenon that lends itself to the concept of follicular targeting of drugs.[22]

It follows that in relationship to the integral protection against the passage of xenobiotics in general, and drugs specifically, the barrier function of the interfollicular stratum corneum is even more potent than previously believed, whereas more research is needed relative to the follicular pathway. Recent investigations hint to the presence of active follicles (open to penetration) and passive ones.[11]

PENETRATION PATHWAYS In principle, three penetration pathways are possible: the intercellular penetration, inside the lipid layers around the corneocytes, the follicular penetration, and the intracellular penetration.

Although in the past, the transcorneal penetration was assumed to be the only penetration pathway, recent investigations, as cited above in Appendages, have demonstrated that penetration via the hair follicles should be taken into consideration.[29–31]

Up to the present time, no evidence is available that topically applied substances pass the skin barriers by means of the intracellular route.

Pathways across the Stratum Corneum. Several studies have directly visualized penetration pathways across the stratum corneum by electron microscopy. For example, osmium vapor can be used to precipitate *n*-butanol that has penetrated the stratum corneum.[32] After a brief (5 to 60 second) exposure of murine or human stratum corneum, the alcohol was found to be enriched in the intercellular spaces (threefold), although significant levels were also found in the corneocytes. By using a different approach that involved rapid freezing, water, ethanol, and cholesterol were also found preferentially concentrated in the intercellular lipid spaces.[33] Similarly, the penetration of mercury chloride through the intercellular lipid can be detected following precipitation with ammonium sulfide vapor.[34]

However, in most of these investigations, there was also significant localization of compounds in the corneocytes, more prevalent in the upper layers (stratum disjunctum). Thus, corneocytes undergoing desquamation appear to be relatively permeable, even to rather bulky ions such as mercury. There is additional evidence that other compounds can and do penetrate corneocytes. It is well established, for example, that occlusion or immersion of skin in a bath leads to swelling of the corneocytes, consistent with the entry of water. Other compounds have also been localized in corneocytes, such as the anionic surfactants that are bound to keratins. Low-molecular-weight moisturizers such as glycerol are likely to partition into the corneocytes and alter their water-binding capacity. Thus, the penetration of compounds into corneocytes cannot be excluded from considerations of percutaneous absorption pathways. The relevance of this step relates to whether it is rate-determining, that is, whether the diffusion of compounds within the intercellular lipid is restricted by the corneocytes.

Pathways across the Hair Follicles. Using the method of differential stripping—a combination of tape stripping with cyanoacrylate surface biopsies—the amount of formulation stored in the hair follicles can be quantified.[35] It was found that nanoparticles were stored 10 times longer in the hair follicles than in the stratum corneum.[14] It should be noted that when topically applied substances penetrate into the hair follicles, they do not necessarily penetrate through the skin barrier into the living tissue, because the hair follicles also have barrier properties.

In the past, there have been several attempts to detect a follicular penetration.[36–38] The experiments were performed on animal and human skin, with different densities of the hair follicles. Unfortunately, in all cases, the properties of the stratum corneum had also changed.

The analysis of the follicular penetration became possible after the development of a method that artificially closes the hair follicles in vivo.[39] Using this method, it was demonstrated that the small molecules, such as caffeine, may penetrate through the skin barrier not only by the transcorneal, but also by the follicular routes.[40]

INTER- AND INTRAINDIVIDUAL VARIATION IN SKIN BARRIER FUNCTION Finally, it is worthwhile to consider the level of inter- and intraindividual variation in skin barrier activity, including that of follicles. The most accurate and reproducible measurement of skin barrier activity is trans-epidermal water loss.[41] The extent of variation of this parameter for the same individual is estimated to be 8 percent by site and 21 percent according to the day of measurement. The variations between individuals are reported to be somewhat larger, ranging from 35 percent to 48 percent.[42] There appear to be no significant gender- or ethnic-dependent differences in skin barrier activity. The skin barrier activity of premature babies (delivered more than 3 weeks premature)[43] is markedly impaired, although skin barrier function appears normal for full-term infants. There seems to be no significant alteration in skin barrier activity as a function of age. Differences in skin barrier activity among different sites have been observed; barrier function can be ranked as arm ~ abdomen > postauricular > forehead.[41]

Viable Tissue

Although the primary barrier to percutaneous absorption lies within the stratum corneum, diffusion within the viable tissue, as well as metabolism and resorption, also influence the bioavailability of compounds in specific skin compartments. These processes are interrelated, and factors that increase the rate of one of these processes inevitably influence the others. Because the development of dermatologic formulations is often focused on "targeted" delivery to living tissues, the manipulation of these processes offers a clear-cut rationale for increasing the therapeutic efficacy of dermatologic drugs.

The passage of compounds from the stratum corneum into the viable epidermis results in a substantial dilution. This is not only the relatively larger volume of the epidermis as compared with that of the stratum corneum, but also the lower resistance to diffusion within viable tissues, approximately corresponding to that of an aqueous protein gel.[42] Drug concentrations of 10^{-4} to 10^{-6} M may be attained in the epidermis and dermis for substances that permeate readily. Although the actual concentration gradient of a compound is affected both by the physicochemical properties of the compounds as well as by the duration of application, a concentration gradient is present at all

times. In other words, strategies to enhance percutaneous absorption generally result in a relatively uniform and parallel increase in the concentration of compounds in all compartments.

SKIN METABOLISM

The skin contains a wide range of enzymatic activities, including phase I oxidative, reductive, hydrolytic, and phase II conjugation reactions, as well as a full complement of drug-metabolizing enzymes.[44] Metabolic activity is a primary consideration in the design of prodrugs and may influence the bioavailability of drugs delivered via dermatologic or transdermal formulations. Alterations in skin metabolism have been implicated in a range of diseases, including hirsutism and acne, and they may be relevant to the risk of topical exposure to carcinogens. Metabolic processing of antigens by Langerhans cells is involved in the presentation of allergens to the immune system. Thus, metabolism in skin compartments plays a significant role in determining the fate of a topically applied active compound.

Significant cutaneous metabolism has been demonstrated for a wide variety of compounds of differing physicochemical properties, including the steroid hormones estrone, estradiol, and estriol, as well as glucocorticoids, prostaglandins, retinoids, benzoyl peroxide, aldrin, anthralin, 5-fluorouracil, nitroglycerin, theophylline, and propranolol.[31] Recently, it has been shown that arylamine-type hair dye ingredients are also subject to metabolism in human and animal skin, resulting in *N*-acetylated metabolites.[45–47] The enzyme responsible is believed to be epidermal *N*-acetyltransferase-1.[45] For example, cutaneous metabolism reduced the systemic bioavailability of nitroglycerin administered in a transdermal drug formulation in rhesus monkeys by 16 percent to 21 percent and hydrolyzed virtually 100 percent of a salicylate diester.[48] It is convenient to classify metabolic reactions in terms of their co-factor dependence. Processes that require co-factors are likely to be energy dependent, and these are located within viable tissues. Among the best-studied examples are the interconversion of steroids (e.g., estrone and estradiol), and the oxidation of polycyclic aromatic hydrocarbons with mixed-function monooxygenases. In contrast, co-factor-independent processes involve catabolism and may be located outside of viable tissues, that is, in the transition region between the stratum corneum and stratum granulosum. The best characterized of these involve hydrolytic reactions such as non-specific ester hydrolysis.

Metabolic activity is found in (1) skin-surface microorganisms, (2) appendages, (3) the stratum corneum, (4) the viable epidermis, and (5) the dermis. In considering the site of the most significant metabolism, one has to take into account the relevant enzymes and their specific activity, as well as their capacity relative to the size of the compartment. Thus, although the level of many enzymes is highest in the epidermis, the relatively large size of the dermal compartment may result in a significant role in the metabolism of topically applied substances. A further consideration is that enzymes involved in cutaneous metabolism may be induced upon exposure to xenobiotics. This has been well described for various mixed-function monooxygenases.[49] Finally, the qualitative and quantitative extrapolation of results from animal models to humans is uncertain, owing to the significant species differences in the metabolism of compounds.

Percutaneous absorption and metabolism of compounds can be viewed as two events in kinetic competition with each other.[50] Generally, compounds that remain in the skin for longer periods of time undergo significantly more metabolism. Furthermore, the type of metabolism of a substance may also be influenced by the nature of its formulation, as illustrated by investigations on the metabolism of several transdermal nitroglycerin formulations.[51] The inclusion of enhancers in the formulation not only increased the bioavailability of the nitroglycerin but also the ratio of one metabolic compound (1,2-glyceryl dinitrate) in relation to another (1,3-glyceryl dinitrate). This may limit the suitability of in vitro experiments for estimating the significance of cutaneous metabolism because the vasculature is not functional in vitro. It further emphasizes that it is difficult to extrapolate quantitatively the level of metabolism obtained for different formulations. This has significant implications for the estimation of bioequivalence.

However, despite the variety of skin-associated metabolic processes, the extent of metabolism is normally modest, that is, in the order of 2 percent to 5 percent of the absorbed compounds, although for N-acetylation of arylamines, metabolism may be quantitative.[47] Metabolism is limited not only by the relatively short period of time that a compound spends in the viable layers of the skin, but also by the overall low level of enzyme activity. Thus, under many circumstances, the available enzymes are saturated by the level of compound undergoing percutaneous absorption.[44]

RESORPTION

Resorption, defined as the uptake of compounds by the cutaneous microvasculature, is directly related to the surface area of the exchanging capillaries as well as their blood flow. Total blood flow to the skin may vary up to 100-fold, a process primarily regulated by vascular shunts, but also by recruitment of new capillary beds. It is estimated that, under resting conditions, only 40 percent of the blood flow passes via exchanging capillaries capable of acting as a sink for absorbed compounds. However, this value demonstrates considerable variation between body sites, individuals, and species and is influenced by disease states and environmental conditions. In particular, changes in temperature and humidity as well as the presence of vasoactive compounds may directly influence skin blood flow.[52]

For most compounds and situations, resorption does not limit the delivery of compounds to the central compartment after topical applications. This is a result of the relatively high resistance to diffusion within the stratum corneum as compared with uptake by the vasculature. However, for compounds or situations in which diffusion across the stratum corneum is rapid, resorption limits the maximum rate of absorption.[52] The evidence that resorption can limit the delivery of compounds to the central compartment comes primarily from studies that examined the influence of blood flow on this process. The percutaneous absorption of methyl salicylate is increased by elevated ambient temperature or strenuous exercise, an observation consistent with increased resorption as a result of cutaneous blood flow.[53] Moreover, intravenously administered nicotine (a vasoconstrictor) reduces the percutaneous absorption of topically applied nicotine.[54] Regional differences in the percutaneous absorption of piroxicam, a nonsteroidal anti-inflammatory agent, are dependent upon the local vasculature rather than upon skin barrier function.[55] Perhaps the most convincing evidence that resorption can limit delivery to the vasculature comes from in vitro studies on the perfused porcine skin flap.[56]

An additional consideration is that the rate of resorption may indirectly influence the diffusion of compounds to the underlying musculature, tissues, and joints.[57] The principle of locally enhanced delivery to underlying muscula-

ture has been demonstrated for piroxicam as well as several local anesthetic preparations.[58]

INFLUENCE OF PATHOLOGIC PROCESSES ON SKIN BARRIER FUNCTION

Reduced skin-barrier function has been observed in a number of pathologic conditions, including the ichthyoses,[59,60] psoriasis,[22,61] atopic dermatitis,[62] and contact dermatitis.[63] It is generally accepted that this is attributable to structural alterations in the stratum corneum.[22] These structural deficiencies may arise from an absence of an enzyme or structural protein in the underlying viable tissues or may be related to the improper formation of the stratum corneum resulting from an increase in keratinocyte proliferation. Thus, in individuals predisposed to a defective barrier, a minor perturbation may become amplified as the skin "attempts to compensate" by increasing keratinocyte proliferation.[64] A further consideration is that the homeostatic mechanisms responsible for recovery of barrier activity after perturbation may be altered in some diseases or physiologic states.

For example, whereas the skin of aged people exhibits normal barrier function, the recovery of barrier activity after perturbation is markedly reduced.[59,60] This kinetic basis for reduced barrier function may also account for interindividual variation in barrier function and/or the apparently increased susceptibility of certain individuals to contact dermatitis.[63]

CHAPTER 216

Topical Corticosteroids

Isabel C. Valencia
Francisco A. Kerdel

MECHANISM OF ACTION

Corticosteroids have specific and nonspecific effects that are related to different mechanisms of action, including: anti-inflammatory, immunosuppressive, antiproliferative, and vasoconstrictive effects. Most of the effects of corticosteroids on cells are mediated by binding of the corticosteroid to its receptor in the cytosol, followed by translocation of the drug-receptor complex to a region of the nuclear DNA known as the *corticosteroid responsive element*, where it is then able to stimulate or inhibit transcription of the adjacent genes, thus regulating the inflammatory process.[1]

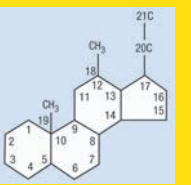
Anti-Inflammatory Effects

Corticosteroids are thought to exert their potent anti-inflammatory effects by inhibiting the release of phospholipase A_2, an enzyme responsible for the formation of prostaglandins, leukotrienes, and other derivatives of the arachidonic acid pathway. Corticosteroids also inhibit transcription factors, such as activator protein 1 and nuclear factor κB, that are involved in the activation of pro-inflammatory genes. Genes known to be upregulated by corticosteroids and that play a role in the resolution of inflammation include lipocortin and p11/calpactin-binding proteins, both involved in the release of arachidonic acid.[1–3] Lipocortin I inhibits phospholipase A_2, reducing the release of arachidonic acid from phospholipids.[1,4,5] Corticosteroids also decrease the release of interleukin 1α (IL-1α), an important pro-inflammatory cytokine, from keratinocytes.[1,6] Other proposed mechanisms for the anti-inflammatory effects of corticosteroids include inhibition of phagocytosis and stabilization of lysosomal membranes of phagocytizing cells.[7]

Immunosuppressive Effects

The effectiveness of corticosteroids is, in part, also due to their immunosuppressive properties. Corticosteroids suppress the production and effects of humoral factors involved in the inflammatory response, inhibit leukocyte migration to sites of inflammation, and interfere with the function of endothelial cells, granulocytes, mast cells, and fibroblasts.[1,8–10] Several studies have shown that corticosteroids can cause mast cell depletion in the skin.[11] Experiments also show that topical corticosteroids cause local inhibition of chemotaxis of neutrophils[12] in vitro, and decrease

TOPICAL CORTICOSTEROIDS AT A GLANCE



- The most frequently prescribed of all dermatologic drug products.
- Are effective at reducing the symptoms of inflammation, but do not address the underlying cause of the disease.
- Topical glucocorticoid research has focused on strategies to optimize potency while minimizing side effects.
- The new molecules have an overall higher anti-inflammatory effect, good compliance (only once daily application), rarely induce cross-sensitivity reactions and have weak atrophogenic properties.

TABLE 216-1
Potency Ranking of Selected Topical Corticosteroid Preparations[a]

Generic Name	Brand Name
Class 1—Superpotent	
Betamethasone dipropionate 0.05% optimized vehicle	Diprolene gel/lotion/ointment
Clobetasol propionate 0.05%	Clobex lotion/spray
	Olux foam
	Temovate cream/emollient cream/ gel/ointment
Diflorasone diacetate 0.05%	Psorcon ointment
Fluocinonide 0.1% optimized vehicle	Vanos cream
Flurandrenolide, 4 mg/cm^2	Cordran tape
Halobetasol propionate 0.05%	Ultravate cream/ointment
Class 2—Potent	
Amcinonide 0.1%	Cyclocort ointment
Betamethasone dipropionate 0.05%	Diprolene AF cream
	Diprosone ointment
Desoximetasone 0.25%	Topicort cream/ointment
Desoximetasone 0.5%	Topicort gel
Diflorasone diacetate 0.05%	Florone ointment
	Maxiflor ointment
Fluocinonide 0.05%	Lidex cream/gel/ointment
Halcinonide 0.1%	Halog cream/solution/ointment
Mometasone furoate 0.1%	Elocon ointment
Class 3—Potent, upper mid-strength	
Amcinonide 0.1%	Cyclocort cream/lotion
Betamethasone dipropionate 0.05%	Diprosone cream
Betamethasone valerate 0.1%	Valisone ointment
Diflorasone diacetate 0.05%	Florone cream
	Maxiflor cream
	Psorcon E cream
Fluocinonide 0.05%	Lidex E cream
Fluticasone propionate 0.005%	Cutivate ointment
Class 4—Mid-strength	
Betamethasone valerate 0.12%	Luxiq foam
Clocortolone pivalate 0.1%	Cloderm cream
Desoximetasone 0.05%	Topicort LP cream
Fluocinolone acetonide 0.025%	Synalar ointment
Flurandrenolide 0.05%	Cordran ointment
Hydrocortisone probutate 0.1%	Pandel cream
Hydrocortisone valerate 0.2%	Westcort ointment
Mometasone furoate 0.1%	Elocon cream/lotion
Prednicarbate 0.1%	Dermatop ointment
Triamcinolone acetonide 0.1%	Kenalog ointment
Class 5—Lower mid-strength	
Betamethasone dipropionate 0.05%	Diprosone lotion
Betamethasone valerate 0.1%	Valisone cream/lotion
Fluocinolone acetonide 0.025%	Synalar cream
Flurandrenolide 0.05%	Cordran cream, lotion
Fluticasone propionate 0.05%	Cutivate cream
Hydrocortisone butyrate 0.1%	Locoid lipocream
Hydrocortisone valerate 0.2%	Westcort cream
Prednicarbate 0.1%	Dermatop emollient cream
Triamcinolone acetonide 0.1%	Kenalog cream/ lotion
Class 6—Mild strength	
Alclometasone dipropionate 0.05%	Aclovate cream/ointment
Desonide 0.05%	DesOwen cream/lotion/ointment
	Tridesilon cream
Fluocinolone acetonide 0.01%	Synalar cream/solution
	Derma-Smoothe/FS oil
Class 7—Least potent	
Topicals with dexamethasone, flumethasone, hydrocortisone	
Methylprednisolone, prednisolone	

[a]It is the general policy of this book not to use trade names. In this case, this rule is broken to facilitate easier reading.

the number of Ia$^+$ Langerhans cells[13] in vivo. Corticosteroids reduce eosinophilia in patients with asthma. They also reduce T-cell proliferation and induce T-cell apoptosis, in part from inhibition of the T-cell growth factor IL-2.[1,14] In addition, several cytokines are directly affected by corticosteroids, including IL-1, tumor necrosis factor-α, granulocyte-macrophage colony-stimulating factor, and IL-8. These effects may also be a result of the steroid action on antigen presenting cells.[15]

Antiproliferative Effects

The antiproliferative effect of topical corticosteroids is mediated by inhibition of DNA synthesis and mitosis, partly explaining the therapeutic action of these drugs in scaling dermatoses.[16] Fibroblast activity and collagen formation are also inhibited by topical corticosteroids.[17]

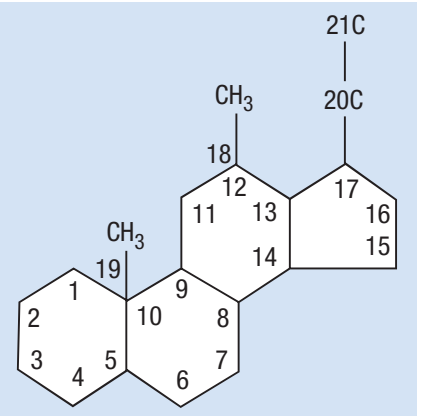
Vasoconstriction

The mechanism by which corticosteroids induce vasoconstriction is not yet completely clear. It is thought to be related to inhibition of natural vasodilators such as histamine, bradykinins, and prostaglandins.[1,18,19] Topical steroids cause capillaries in the superficial dermis to constrict, thus reducing erythema. The ability of a given corticosteroid agent to cause vasoconstriction usually correlates with its anti-inflammatory potency, and thus, vasoconstriction assays are often used to predict the clinical activity of an agent. These assays, in combination with double-blind clinical trials, have been used to separate the topical corticosteroids into seven classes based on potency. Class 1 includes the most potent, while class 7 contains the least potent. Table 216-1 lists many of the available topical corticosteroids according to this classification. Notice that the same drug can be found in different potency classifications depending on the delivery vehicle used.

PHARMACOKINETICS

Corticosteroids have a basic skeletal structure comprising 17 carbon atoms arranged in three six-membered rings and one five-membered ring. Modifications of cortisol (Fig. 216-1), by addition or alteration of functional groups at certain positions, have led to compounds with variable anti-inflammatory potency, glucocorticosteroid versus mineralocorticoid activity, and adverse effects.

Topical corticosteroid research has focused on strategies to optimize potency



▲ **FIGURE 216-1** Basic steroid molecule.

while minimizing side effects. One strategy is to develop compounds with enhanced anti-inflammatory effects and minimal unwanted atrophogenic and adrenal suppressive effects. In this sense, progress has been made with the development of glucocorticoid molecules that, while retaining high activity in the skin following topical application, are quickly broken down into inactive metabolites, thereby mitigating systemic and possibly some local toxic effects ("soft" glucocorticoids). Some of the newest of these compounds include the di-esters 17,21 hydrocortisone aceponate and hydrocortisone 17-butyrate-21-propionate, prednicarbate, methylprednisolone aceponate, alclometasone propionate, and carbothioates such as fluticasone propionate.[1,24] Hydrocortisone aceponate, prednicarbate, and methylprednisolone aceponate have significant anti-inflammatory effects, but the least capacity to induce skin atrophy; therefore, they can be used to treat areas such as the face, the scrotum, and large body surface areas in children, with minimal adverse effects.[1,25] Fluticasone propionate is classified as a potent corticosteroid with lower potential to cause skin atrophy and adrenal suppression. It offers the advantage of once daily application and infrequent local allergic reactions. Mometasone furoate also has highly anti-inflammatory effects with low incidence of adrenal suppression.[1]

INDICATIONS

Topical corticosteroids are recommended for their anti-inflammatory activity in inflammatory skin diseases, but they can also be used for their antimitotic effects and their capacity to decrease the synthesis of connective tissue molecules.[1] Certain variables must be considered when treating skin disorders with topical glucocorticoids. For example, the responsiveness of diseases to topical glucocorticoids varies. In this setting, diseases can be divided into the three categories shown in Table 216-2: highly responsive, moderately responsive, and least responsive.

Pediatric Uses

Topical glucocorticoids are highly effective, and few side effects are observed when a low-potency preparation is used for brief periods of time without occlusion in children. However, children and, in particular, infants, are at an increased risk of absorbing topical corticosteroids for several reasons. Because they have a higher ratio of skin surface area to body weight, application to a given area results in a greater potentially systemic dose of steroid. Infants may also be less able to metabolize potent glucocorticoids rapidly.[26] Premature infants are especially at risk because their skin is thinner and the penetration rate of topically applied drugs is greatly increased.[27] Application of topical steroids to the diaper area results in occlusion of the steroid by the diaper, and increased penetration occurs. Excess absorption of topical glucocorticoids can suppress endogenous cortisol production. Consequently, subsequent cessation of topical steroid therapy after an extended treatment period can, albeit rarely, result in an addisonian crisis. Deaths from addisonian crisis have been reported with the use of topical steroids,[28] and the risk of this occurring is greater in children. Chronic suppression of cortisol production can also lead to growth retardation. A morning plasma cortisol level can be performed to screen for adrenal suppression. If suppression is present, the child should be slowly weaned from the steroids to prevent these complications.

Geriatric Uses

Elderly patients similarly can have thin skin, which allows for increased penetration of topical glucocorticoids. They are also more likely to have pre-existing skin atrophy secondary to aging and may be diaper-dependent, so the same precautions used in the treatment of infants should be used when treating elderly patients.

Uses in Pregnancy

Appropriate human studies using topical glucocorticoids in pregnancy have never been undertaken. Studies in animals, however, show that topical steroids are systemically absorbed and may cause fetal abnormalities, especially when used in excessive amounts, under occlusive dressings, for prolonged periods of time, or when the more potent agents are used. However, numerous studies of pregnant patients taking systemic glucocorticoids throughout pregnancy show no increases in the incidence of fetal abnormalities. Most topical steroids are rated by the U.S. Food and Drug Administration as category C drugs, which imply that caution must be exercised when used in pregnancy. It is currently unknown whether topical glucocorticoids are excreted in breast milk; however, they should be used with caution in breast-feeding mothers and should never be used on the breasts before breast-feeding.

DOSING REGIMEN

The frequency of topical application of corticosteroids was developed in an empirical manner, with most textbooks and physicians recommending multiple daily use. Lagos and Maibach observed in a recent review of the literature that for su-

TABLE 216-2
Responsiveness of Dermatoses to Topical Application of Corticosteroids

HIGHLY RESPONSIVE	MODERATELY RESPONSIVE	LEAST RESPONSIVE
• Psoriasis (intertriginous)	• Psoriasis	• Palmo-plantar psoriasis

	• Lichen simplex chronicus	• Granuloma annulare
		• Necrobiosis lipoidica diabeticorum
		• Sarcoidosis
		• Allergic contact dermatitis, acute phase
		• Insect bites

perpotent corticosteroids, once-daily application was as beneficial as twice-daily application. Likewise, there was no difference or only a slight difference with once or twice daily application of potent or moderately potent corticosteroids. The authors concluded that once-daily application of topical corticosteroids may be preferable, may decrease the risks of side effects and tachyphylaxis, decrease the cost of therapy, and improve the patient's compliance.[29] Tachyphylaxis has been demonstrated in experimental conditions by diminished vasoconstriction, rebound of DNA synthesis, and recovery of histamine wheals after application of topical steroids in patients with a history of long-term topical steroid usage.[30]

As a working rule, not more than 45 g/week of potent or 100 g/week of weak or moderately potent topical corticosteroid should be applied (without occlusion) if systemic absorption is to be avoided.[31]

CLINICAL FORMULATIONS

INITIATING THERAPY

Before choosing a topical glucocorticoid preparation, one must consider the area of the body that is to be treated because regional differences greatly affect the activity of the topical agent. Penetration of the glucocorticoid varies according to the skin site, which, in turn, is related to the thickness of the stratum corneum and the vascular supply to the area. For example, penetration of topical steroids through the eyelids and scrotum is four times greater than for the forehead and 36 times greater than for the palms and soles. Inflamed, moist, and denuded skin also shows increased penetration. Areas of the body where the skin is inherently thin not only allow for increased penetration of the drug but are more susceptible to develop side effects than other areas where the skin is thick. Potent topical steroids (classes 1 and 2) should rarely, if ever, be used in the areas with the highest level of penetration, such as the eyelids. Some general rules should be remembered when initiating topical corticosteroids[1,34]:

- Highly responsive diseases will usually respond to weak steroid preparations, whereas less-responsive diseases require medium or high-potency topical steroids.
- Low-potent preparations should be used on the face and intertriginous areas.
- Very potent corticosteroids frequently under occlusion are usually required on hyperkeratotic or lichenified dermatoses and for disease of the palms and soles.

MONITORING THERAPY

Application of corticosteroids to large surface areas, occlusion, higher concentrations, or more potent derivatives directly increase the risk of hypothalamic-pituitary-axis (HPA) suppression. If the latter is suspected, laboratory analyses that include a complete blood cell count, a chemistry panel, and a baseline morning cortisol level should be performed. In a patient with confirmed HPA suppression, the simultaneous institution of oral steroid supplementation and a reduction of potency and amount of topical steroid is needed.[35]

RISKS AND PRECAUTIONS

Local as well as systemic side effects have been documented with the use of topical corticosteroids. Under normal conditions, up to 99 percent of the applied topical corticosteroid is removed from the skin, and only 1 percent is therapeutically active. Cutaneous adverse effects can result from the small percentage of percutaneously absorbed corticosteroid or may also result from its transient presence onto the skin. Continued use of topical corticosteroids may also lead to tachyphylaxis.[36]

Consideration for prescribing topical corticosteroids to prevent side effects[1,34,37,38]:

- Highly potent formulations should be used for short periods (2 to 3 weeks) or intermittently. Once disease control is partially achieved, the use of a less potent compound should be initiated.
- Reduce frequency of application (e.g., application only in the morning, alternate-day therapy, weekend use) once disease control is partially achieved.
- Topical corticosteroids should be avoided on ulcerated or atrophic skin, and on skin with co-existent infectious dermatoses.
- Sudden discontinuation should be avoided after prolonged use to prevent rebound phenomena.
- Special guidelines should be followed when treating certain body areas (e.g., intertriginous areas) or certain populations (e.g., children or the elderly) to prevent the occurrence of local or systemic adverse effects.
- Laboratory tests should be considered if systemic absorption of corticosteroids is suspected.
- Use combination therapy when clinically indicated (e.g., addition of topical tretinoin or keratolytics).

COMPLICATIONS

Local adverse effects of topical corticosteroid use are more prevalent than systemic reactions.[36]

Atrophic Changes

Skin atrophy is the most common adverse effect of corticosteroid therapy. Dermal atrophy develops from the direct antiproliferative effects of topical corticosteroids on fibroblasts, with inhibition of collagen and mucopolysaccharide synthesis, resulting in loss of dermal support. Fragmentation and thinning of elastic fibers develop on the upper layers, whereas deeper fibers form a compact and dense network.[31] As a result of these atrophic changes, there is vascular dilatation, telangiectasias, purpura, easy bruising, stellate pseudoscars (purpuric, irregularly shaped, and hypopigmented atrophic scars), and ulceration. Although atrophy is, to some extent, reversible, formation of striae, visible linear scars that form in areas of dermal damage presumably during mechanical stress, are permanent.

Acneiform Reactions

The development or exacerbation of dermatoses of the face, including steroid rosacea, acne, and perioral dermatitis, is a well-known effect of topical corticosteroids. Although steroids initially lead to the suppression of inflammatory papules and pustules, patients become addicted because they notice that the lesions flare when treatment is withdrawn. This frequently leads to the continued use of greater potency topical corticosteroids. For these reasons, steroid use should be discouraged in the treatment of rosacea and perioral and periocular dermatitis.

Prolonged corticosteroid treatment can also result in "steroid acne," which is characterized by crops of dense, inflamed pustules in the same developmental stage. These lesions occur on the face, chest, and back (see Chap. 78).

Hypertrichosis

Hypertrichosis occurs rarely in women and children who apply potent cortico-

steroids to the face. The mechanism is still unknown.[1]

Pigmentary Changes

Decreased pigmentation is a common side effect of topical steroid use. The pigment generally returns after discontinuation of therapy.

Development of Infections

Topical corticosteroids are responsible for exacerbating and/or masking cutaneous infectious diseases. The incidence of skin infection during corticosteroid therapy varies but is probably between 16 percent and 43 percent.[39] Tinea versicolor, disseminated *Alternaria* infection, and dermatophytosis, including tinea incognito (masked dermatophyte infection), can develop. Granuloma gluteale infantum, characterized by reddish-purplish granulomatous lesions on the diaper area, is a well-known complication of diaper dermatitis that is being treated with corticosteroids. *Candida albicans* is commonly recovered in these patients. Topical corticosteroids have also an effect on prolongation or mitigation of herpes simplex, molluscum contagiosum, and scabies infection.

Allergic Reactions

Persistence or worsening of skin diseases occurs as a result of contact hypersensitivity to topical corticosteroids. The prevalence to topical corticosteroid sensitization ranges between 0.2 percent and 6.0 percent, and increases with prolonged exposure and the selection of certain drugs.[36,40,41] The allergen may be the vehicle, the preservative, or the steroid itself. Most topical steroid ointments are free of preservatives and are less likely than other topical agents and steroid creams to cause an allergic or irritant contact dermatitis. The most common preservatives that cause allergic contact dermatitis include parabens, polyethylene glycol, and benzyl alcohol (Table 216-3). Fragrance and local anesthetics are also sensitizers that may be included in the topical preparations.

TABLE 216-3
Potential Contact Sensitizers in Topical Corticosteroids

- Parabens
- Propylene glycol
- Benzyl alcohol
- Chlorocresol
- Ethylenediamine hydrochloride
- Isopropyl palmitate
- Polysorbate 60
- Stearyl alcohol
- The corticosteroid itself

Systemic Adverse Effects

OCULAR EFFECTS The development of glaucoma from the use of topical corticosteroids around the eye has been described.[46–48] Prolonged corticosteroid use has also led to vision loss.[49]

SUPPRESSION OF THE HYPOTHALAMIC-PITUITARY-ADRENAL AXIS Suppression of the HPA axis has been described with the use of potent topical corticosteroids. Iatrogenic Cushing syndrome, corticosteroid-related Addison crises, and retarded growth of children have all been described after prolonged use of potent topical corticosteroid preparations. A dose of 14 g/week of clobetasol propionate or 49 g/week of betamethasone dipropionate is sufficient to suppress plasma cortisol levels.[17]

METABOLIC SIDE EFFECTS Increased glucose production and decreased glucose use induce hyperglycemia and may lead to diabetes mellitus.

CHAPTER 217

Topical Retinoids

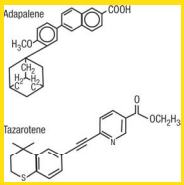
Sewon Kang
John J. Voorhees

In topical preparations, retinoids are widely used as prescription drugs as well as cosmeceuticals. In some of these products, retinoids are naturally occurring compounds while others are synthetic molecules. Their potency and effectiveness may vary depending on the nature and concentration of the retinoids, the need for metabolic conversion to active compounds, and the formulation that influences skin penetration. Yet, as a group, retinoids share predictable pharmacology in eliciting human skin responses due to the fact that retinoid effects are primarily mediated through their intranuclear retinoid receptors acting as transcription factors. Indeed, the discovery and characterization of retinoic acid receptors (RARs) and retinoid X receptors (RXRs) has been pivotal to our understanding of the retinoid action mechanism and gave rise to the idea that retinoids act similarly to hormones.[1,2] In 1976, Michael Sporn and his colleagues originally defined retinoids as both the naturally occurring compounds with vitamin A activity and the synthetic analogues of retinol. This concept is no longer adequate. Now, retinoid is defined as any molecule that, by itself or through metabolic conversion, binds to and activates the RARs, thereby eliciting transcriptional activation of retinoic acid–responsive genes that results in specific biologic responses.

RETINOID RECEPTORS

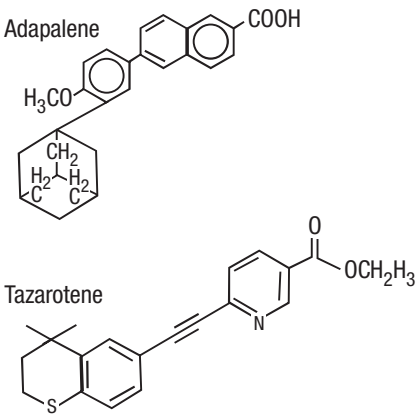
The discovery and characterization of RARs as having molecular features that are similar to steroid/thyroid hormone

RETINOIDS AT A GLANCE



- Definition: Any molecule that by itself or through metabolic conversion binds to and activates retinoic acid receptors.
- Retinoid receptors: Ligand-dependent transcription factors.
- Predominant retinoid receptors in human skin: Retinoic acid receptor α (RAR-α), RAR-γ, retinoid X receptor α (RXR-α), and RXR-β.
  - RAR-γ/RXR-α heterodimers bind to retinoic acid–responsive elements and are responsible for retinoid signaling.
- Clinical use of topical retinoids:
  - Approved indications—acne, psoriasis and photoaged skin.
  - Unapproved indications with clinical studies supporting benefit—post-inflammatory hyperpigmentations, melasma, and early stretch marks.
- Local skin irritation: Mainly due to retinoid-induced epidermal hyperplasia. Clinical use should be titrated based on the severity of local reactions.

receptors were landmark findings.[1,2] A characteristic common to these receptors is that they bind to regulatory regions in DNA called *hormone response elements*, or *target sequences*, and activate gene transcription in a ligand-dependent manner. Therefore, they are referred to as *ligand (hormone)-dependent transcription factors*. These receptors bind to specific DNA sequences as dimers. Unlike receptors for the steroid hormones, which form homodimers (two identical monomers); RAR, vitamin D receptor (VDR), and thyroid hormone receptors (TR) bind to their elements with greater affinity as heterodimers (two different monomers). The critical partner for heterodimerization and ultimate functioning of RAR, VDR, and TR is the RXR,[3] whose physiologic ligand is 9-*cis* retinoic acid.[4] The ability of RXRs to interact with many receptors suggests their importance as regulatory proteins. There are three different members of RAR (α, β, and γ) and RXR (α, β, and γ), each encoded by different genes. Furthermore, each of the receptors has isoforms, adding to the diversity of retinoid receptors.



▲ **FIGURE 217-1** Chemical structures of the synthetic retinoids adapalene and tazarotene.

RECEPTOR-SELECTIVE RETINOIDS

The identification and functional characterization of retinoid receptor families cleared the way for drug discovery. Synthetic molecules could be screened for their ability to bind to and activate specific receptors. Many of these compounds have no structural similarities to all-*trans* retinol or retinoic acid, yet are still considered retinoids by virtue of their ability to activate the receptor(s), therefore mediating the retinoid effect. Adapalene and tazarotene are two synthetic retinoids that fit this description and have been used topically in humans (Fig. 217-1). Adapalene has restricted receptor specificity, possessing poor affinity for RAR-α, higher affinity for RAR-β and -γ, and no interaction with RXR-α.[5] Tazarotene cannot directly bind to RARs or RXRs. However, its metabolite, tazarotenic acid, has receptor selectivity for RARs (RAR-β > RAR-γ > RAR-α),[6] and is felt to be the principal active form.

RETINOID RECEPTORS IN HUMAN SKIN

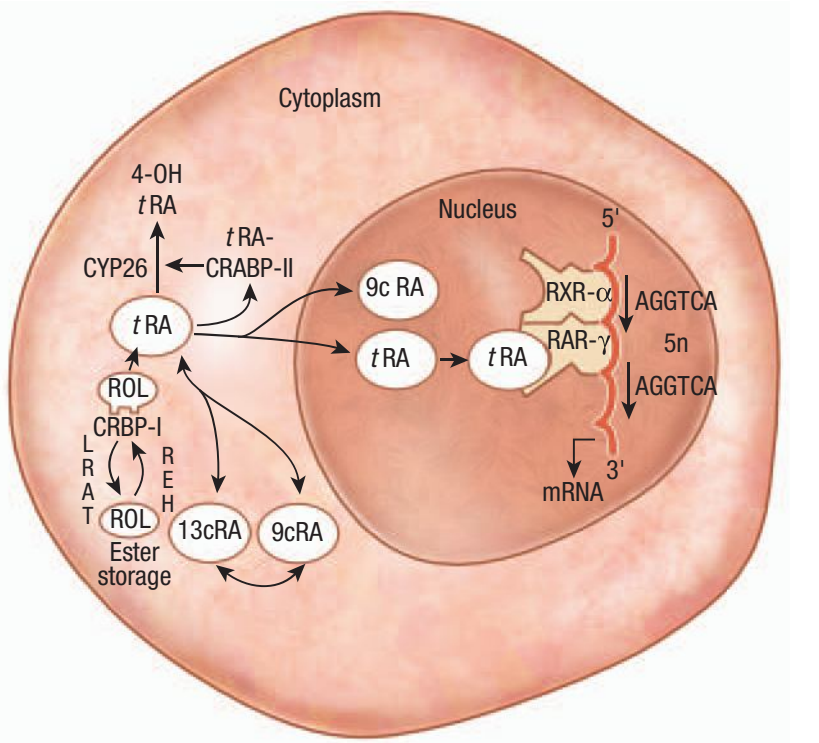
Systematic analysis of relative levels of each RAR and RXR has been made in human skin and shows that the human epidermis expresses RAR-α, RAR-γ, RXR-α, and RXR-β messenger RNAs (mRNAs).[7,8] RXR-γ mRNA is undetectable, and the transcript for RAR-β is barely detectable. These relative levels of retinoid receptor mRNAs mirror their relative protein levels. In nuclei from human epidermal cells, there are five times more total RXRs than RARs.[8] For RAR proteins, 87 percent are RAR-γ and 13 percent are RAR-α with no detectable RAR-β. Of the RXR proteins, 90 percent are RXR-α. In gel-shift studies performed on nuclei isolated from human skin and cultured keratinocytes, and in which both cases are expressing their normal endogenous receptors, only RXR-α and RAR(mostly γ) heterodimers bind to retinoic acid–responsive elements (RAREs).[8,9] Neither RAR nor RXR homodimers are detectable. Based on chloramphenicol acetyltransferase reporter gene activity in keratinocytes, the heterodimer requires only the RAR ligand to activate RXR/RAR-bound RAREs. Furthermore, the presence of RXR ligand does not confer additional transactivation induced by RAR ligand. Therefore, at their physiologic levels, RARs and RXRs in human skin bind RAREs as heterodimers and transactivate these response elements in response to RAR, but not to RXR, ligands. However, the RXR is key, as the heterodimer will not bind to the RARE without the presence of the RXR protein. Ultraviolet (UV) irradiation of human skin causes a rapid and significant reduction of retinoid receptors, both RAR-γ and RXR-α.[10] Although this decrease in the receptor levels is transient and returns to pre-UV treatment levels within 2 days, UV irradiation results in functional impairment of receptor-dependent retinoid responsiveness in human skin. Interestingly, pre-treatment of skin with all-*trans* retinoic acid before UV irradiation reduces receptor loss and accelerates receptor recovery.[10]

RETINOID TARGET GENES AND THEIR ACTIVATION CASCADE IN HUMAN SKIN

Retinoid actions are primarily, if not completely, mediated by retinoid receptors. Given that the receptors are transcription factors, the ultimate skin effects of retinoids (phenotypic changes) must be accomplished through regulated gene expression. The best-established mechanism by which retinoid receptors modulate gene expression is activation of retinoid target genes through direct binding to RARE in the gene promoter, thereby stimulating the basal transcriptional machinery. In skin, cellular retinoic acid binding protein (CRABP) II, cellular retinol binding protein (CRBP), retinoic acid 4-hydroxylase (CYP26), and keratin 6—all of which contain RAREs—are regulated by all-*trans* retinoic acid.[11–14] However, the products of these genes are probably not the effectors of the retinoid response and so can-

not account for the pleiotropic effects of retinoids in skin. Undoubtedly, additional RARE-regulated genes will be identified that encode for proteins that function to modulate cutaneous growth and differentiation either directly or indirectly. A likely scenario is that these protein products, in turn, activate other non–RARE-containing genes in a cascading reaction to produce the clinical features of retinoid action in skin (Fig. 217-2).

Molecular description responsible for the most striking histologic feature of all-*trans* retinoic acid–treated skin, the marked thickening of the epidermis, illustrates this point.[11,15] The epidermal hyperplasia is caused by the increased proliferation of basal keratinocytes. An increase is also seen in the number of cell layers expressing the differentiation markers involucrin, loricrin, filaggrin, and epidermal transglutaminase[14] (see Chap. 44). These epidermal changes collectively translate to clinical desquamation and peeling. This hyperproliferative response of epidermis to retinoic acid is mediated by its nuclear receptor, as was demonstrated in transgenic mice expressing either dominant-negative RXR-α[16] or dominant-negative RAR-α[17] mutant proteins targeted to the suprabasal epidermis by the keratin 10 promoter. The mutant proteins impaired retinoid signaling by competing with endogenous RAR-γ/RXR-α heterodimers. In these mice, the ability of topically applied retinoic acid to stimulate proliferation of undifferentiated keratinocytes in the basal layer and resultant peeling of stratum corneum from the surface was significantly reduced.[16,17] Therefore, the epidermal hyperplasia and subsequent peeling alterations are part of the retinoid-specific skin responses. Among the genes regulated by retinoid receptors involved in the cell growth control (keratinocyte proliferation), ligands for epidermal growth factor (EGF) receptor appear to be critically important. In human skin in vivo, topical retinoic acid induces heparin-binding (HB)-EGF and amphiregulin (AR), which stimulate basal cell growth via the cell surface EGF receptor activation.[18,19] Interestingly, neither HB-EGF nor AR possesses any putative RARE. Therefore, a direct modulation of HB-EGF or AR by RARE promoters seems unlikely. Rather, RAR/RXR is likely regulating other transcription factor(s) that would, in turn, regulate AR and HB-EGF gene expression (Fig. 217-3). The identity of such transcription factor(s) remains to be determined.



▲ **FIGURE 217-2** Cellular metabolism of natural retinoids and molecular mechanism of retinoid-specific gene activation. Retinol (ROL) delivered to a cell is bound to cellular retinol binding protein (CRBP)-I. ROL can be esterified, via lecithin:retinol acyltransferase (LRAT), and stored as ROL-esters. Hydrolysis of ROL-ester by its hydrolase (REH) yields free ROL. Sequential oxidation of ROL generates retinoic acid (RA), which is bound to cellular retinoic acid binding protein (CRABP). All-*trans* RA (*t* RA) can be isomerized to 9-*cis* RA (9*c* RA). Hydroxylation of *t* RA by cytochrome-P_{450} enzyme CYP26 generates 4-OH RA, which is relatively inactive. RARs and RXRs are intranuclear receptors for retinoids. In human skin, RAR-γ and RXR-α heterodimers bound to RA-response elements (such as AGGTCA direct repeats) transduce retinoid effects in the presence of RAR ligands. mRNA = messenger RNA.

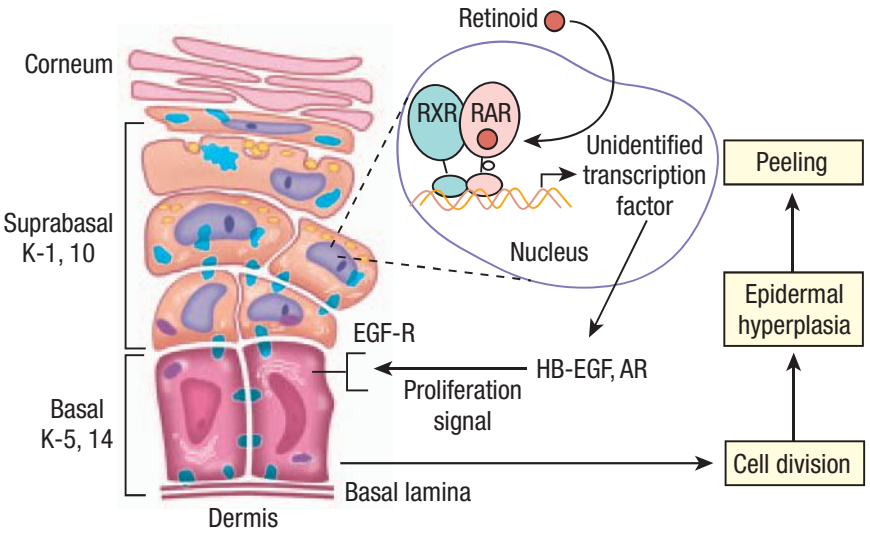
PHARMACOLOGY: NOMENCLATURE

All-*trans* retinoic acid (tretinoin), which binds to and activates RARs, is derived from sequential oxidation of all-*trans* retinol (or vitamin A) and all-*trans* retinaldehyde. It is a 20-carbon molecule that consists of a cyclohexenyl ring, a side chain with four double bonds (all arranged in *trans* configuration), and a carboxylic acid end group (Fig. 217-4A). The numbering of the carbon atoms is as shown in Fig. 217-4B. The terms *9-cis* and *13-cis retinoic acid* refer to stereoisomers of all-*trans* retinoic acid in which the double bond that begins with the ninth and thirteenth carbon atoms, respectively, is in the *cis*- rather than *trans*-configuration. The fourth carbon atom is located in the cyclohexenyl ring of all-*trans* retinoic acid and is involved in a hydroxylation reaction to generate 4-hydroxy-all-*trans* retinoic acid (see Fig. 217-4C). The addition of a hydroxyl group to the cyclohexenyl ring renders the molecule more polar, making it more amenable to excretion/elimination from cells and organisms. It is also much less active biologically. 4-Hydroxy-all-*trans* retinoic acid can be further oxidized to 4-oxo retinoic acid.

A group of compounds referred to as *retinyl esters* functions as the molecular storage form of retinol. The compounds are formed by esterification of retinol with fatty acids (see Fig. 217-4D), which specify the ester. For example, retinyl palmitate is generated when retinol is esterified with palmitic acid. Hydrolysis of retinyl esters regenerates retinol. Finally, β-carotene is a symmetric 40-carbon molecule (twice the number of retinol or retinoic acid) present in green and yellow-orange fruits and vegetables. As suggested by stoichiometry, one molecule of this carotenoid can potentially generate two molecules of retinol by cleavage of the central double bond (see Fig. 217-4E).

Esterification and Oxidation of Retinol

Topical treatment of human skin with all-*trans* retinol increases retinyl ester levels in the epidermal layer by more than 10-fold.[11] This reaction is catalyzed by two



▲ **FIGURE 217-3** Molecular mechanism of retinoid-induced epidermal hyperplasia. Topical application of a retinoid activates retinoic acid receptor/retinoid X receptor (RAR/RXR) heterodimers in suprabasal keratinocytes, causing activation of yet unidentified transcription factors. These, in turn, activate the synthesis of heparin-binding epidermal growth factor (HB-EGF) and amphiregulin (AR). Through activation of epidermal growth factor-receptor (EGF-R), HB-EGF and AR cause proliferation of basal keratinocytes, thereby inducing thickened epidermis and consequent peeling/flaking of the stratum corneum. K = keratin.

enzymes: lecithin/retinol acyltransferase and acyl-coenzyme A/retinol acyltransferase. In human keratinocytes, lecithin/retinol acyltransferase has the predominant retinol-esterifying activity.[20]

Sequential oxidation of all-*trans* retinol forms all-*trans* retinoic acid, with all-*trans* retinaldehyde as the intermediate metabolite. The first step (oxidation of all-*trans* retinol to all-*trans* retinaldehyde) is rate limiting for all-*trans* retinoic acid formation. Topical application of all-*trans* retinol to human skin results in histologic and molecular alterations that mimic those following all-*trans* retinoic acid treatment.[11] These include epidermal hyperplasia caused by keratinocyte proliferation, epidermal spongiosis, compaction of the stratum corneum, and induction of CRBP, CRABP-II, and CYP26.[20,21] In retinol-treated skin, all-*trans* retinoic acid is minimally detectable and is no different from levels found in untreated normal skin. The lack of significant accumulation of all-*trans* retinoic acid in retinol-treated skin is a result of the tightly regulated conversion of retinol to retinaldehyde and the effective hydroxylation of all-*trans* retinoic acid that is formed by CYP26. The observation that all-*trans* retinol and retinoic acid elicit similar responses in human skin, but that retinol does so without detectable increases in retinoic acid levels, indicates that endogenously synthesized retinoic acid is a much more efficient activator of retinoid pathways than exogenously supplied retinoic acid.

Hydroxylation of All-*Trans* Retinoic Acid

In human skin all-*trans* retinoic acid is catabolized primarily to the more polar 4-hydroxy-all-*trans* retinoic acid, which is further metabolized to 4-oxo retinoic acid. 4-Hydroxy retinoic acid is 10-fold less potent in inducing retinoid responses in human keratinocytes and mouse skin than all-*trans* retinoic acid.[22] In untreated normal human skin, CYP26 activity is minimally detectable. Topical administration of all-*trans* retinoic acid or all-*trans* retinol to human skin, however, increases its activity several fold.[21,23] This hydroxylase activity is also induced in skin treated with 9-*cis* or 13-*cis* retinoic acid, but remarkably, it has substrate specificity for the all-*trans* retinoic acid isomer only and does not hydroxylate 9-*cis* or 13-*cis* retinoic acid, retinol, or retinaldehydes.[21] With all-*trans* retinoic acid, CYP26 activity is maximally induced after 24 hours of occlusive treatment. The CYP26 activity can be effectively inhibited by ketoconazole and a related azole, liarozole.[15,23] By blocking this major inactivation pathway of all-*trans* retinoic acid pharmacologically, topical liarozole can serve as a retinoic acid-mimetic or amplify human skin responses to all-*trans* retinol and retinoic acid.[15] This approach of targeting CYP26 has given rise to a novel class of new chemical entities referred to as *retinoic acid metabolism blocking agents* (RAMBAs). Although RAMBAs were introduced to dermatology several years ago, their drug development progress has been slow. A challenge for RAMBAs of the future is to selectively target CYP26 without affecting other enzymes such as steroid metabolizing aromatase or 17,20-lysase.

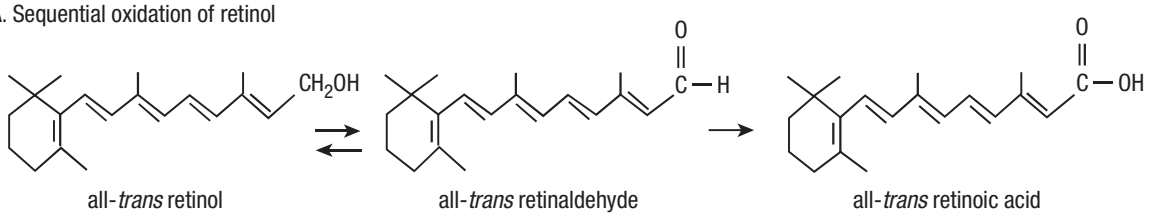
CLINICAL USE

Until quite recently, clinical use of topical retinoids has been limited to all-*trans* retinoic acid. Although the initial use of this retinoid was for actinic keratosis, currently, the only approved dermatologic indications in the United States are for acne and photoaged skin. Topical adapalene and tazarotene have also received approval from the U.S. Food and Drug Administration for acne; tazarotene has also received approval for psoriasis and photoaging.

It is widely accepted that topical retinoids are extremely effective for acne therapy, especially for comedonal lesions. Of the different classes of antiacne medications, retinoids are thought to be the best, if not the only, agents to normalize the abnormal follicular epithelial differentiation/desquamation viewed to be important in the pathogenesis of acne lesions. Therefore, the use of retinoids can also provide protection against the development of new lesions. This prophylactic property is the basis for including topical retinoid in almost all antiacne regimens. A potential for aggravating inflammation exists in treating inflammatory acne (i.e., papules and pustules) with topical retinoids, but when properly administered, this type of acne also responds well to retinoids (see Dosage Schedules and Forms).

Fine wrinkles and dyspigmentation are two salient features of photoaged skin that are improved by topical tretinoin or tazarotene. Several weeks of treatment are required before clinical improvement is appreciated.[24–26] For the effacement of fine wrinkles by topical tretinoin, partial restoration of markedly reduced levels of collagen in sun-exposed skin toward those seen in sun-protected skin appears to be responsible.[25,27] Tretinoin's ability to improve photoaging is specific and does not result from the irritation or retinoid dermatitis frequently produced by this compound.[26] Topical adapalene is not approved for the treatment of photoaging; however, a recent study indicates

A. Sequential oxidation of retinol



all-*trans* retinol | all-*trans* retinaldehyde | all-*trans* retinoic acid

B. All-*trans* retinoic acid and its stereoisomers

that it also holds promise in ameliorating the clinical features of photodamage.[28]

Besides the approved indications, topical retinoids have been demonstrated to be effective in the treatment of several other conditions. Most studies have used tretinoin because it is the first topical retinoid to be developed and has been available the longest. Studied conditions include, but are not limited to, post-inflammatory hyperpigmentation in blacks,[29] actinic dyspigmentation in Chinese and Japanese individuals,[30] melasma,[30,31] and early stretch marks.[32] The controlled studies show more than therapeutic efficacies. They also provide valuable information to dispel some of the myths about retinoid use in humans. For example, African Americans and Asians tolerate topical tretinoin as well as, if not better than,[29–31] Caucasians.[25,33] Furthermore, the often observed retinoid dermatitis does not usually lead to post-inflammatory hyperpigmentation in those with greater constitutive pigmentation.

Many other skin disorders have been reported to be improved by topical retinoids, but most of these have not been rigorously studied, thus their therapeutic claims should be interpreted with caution. Molluscum contagiosum, warts, and various forms of ichthyosis may be improved by topical retinoids to a variable degree. In psoriasis, especially, irritation of treated skin has limited the use. Topical tazarotene, which is approved for psoriasis, does not appear to have fully overcome the irritation problem[34]; thus, it is typically used in combination with topical steroids. The beneficial effects of topical retinoids in treating actinic keratoses have been confirmed through clinical trials.[28] However, there is no role for topical retinoids in the treatment of established cutaneous tumors.

With such a wide variety of skin conditions treatable by topical retinoids, their use has included all age groups, perhaps with the exception of neonates. Similar considerations in dose schedule and forms are made in both young and old patients. The use of topical retinoids in pregnancy is an emotional issue. As discussed in Adverse Effects, teratogenicity is not caused by topical retinoids. However, because none of the dermatologic conditions seen in pregnancy that may respond to topical retinoids (i.e., acne, melasma, stretch marks) is life-threatening to the mother or the fetus, it seems prudent to delay the treatment until after delivery. In a study that demonstrated that early, inflammatory stretch marks were improved by topical tretinoin, all pregnancy-related stretch marks were treated postpartum.[32] Therefore, even in this pregnancy-associated condition, the therapeutic benefit could be achieved by instituting the treatment after delivery.

DOSAGE SCHEDULES AND FORMS

For decades, tretinoin was the only topical retinoid available for clinical use. Under the trade name Retin-A, three different formulations are available for acne therapy: cream (0.025 percent, 0.05 percent, 0.1 percent), gel (0.01 percent, 0.025 percent), and solution (0.05 percent). For photoaging treatment, tretinoin (0.05 percent, 0.02 percent) and tazarotene (0.1 percent) are available as Renova and Avage cream, respectively. A more recent addition to acne therapy, adapalene (Differin) is available in 0.1 percent gel and lotion formulations. For acne and psoriasis, topical tazarotene (0.05 percent and 0.1 percent) is available in gel and cream formulations. Different formulations allow some flexibility in terms of tailoring the therapy to an individual's skin dryness or oiliness.

Regardless of the retinoid preparation or the patient's age, the most important element in topical therapy is patient/guardian education. It must be explained clearly to each patient that, as part of the treatment, local skin irritation, characterized by redness and peeling, can be expected. The concept that clinical improvement correlates with the degree of irritation has been erased through a large, controlled clinical study in which 0.025 percent and 0.1 percent tretinoin were shown to be equally efficacious, but the former was significantly less irritating than the latter.[26] Therefore, unlike most medications for which the dosing schedule may be set as once or twice daily, administration of a topical retinoid should be titrated depending on the skin reaction. For some individuals, it may be applied only twice a week, for others four times a week, and this can be increased, as tolerated, to a once-daily regimen. This method of individualizing topical therapy minimizes unwanted acute retinoid dermatitis.

Under the nonprescription category, there are countless "natural retinoid" preparations with various claims (mostly antiaging) being sold throughout the world. Most of these contain retinyl esters, especially retinyl palmitate, retinaldehyde, or retinol. Whether any of these products can deliver retinoid activity to human skin is subject to question. Percutaneous absorption (especially for retinyl esters), adequate concentrations, and stable formulations (especially for retinol) are some of the important unknowns for this group of products. Based on human in vivo work, all-*trans* retinol and all-*trans* retinaldehyde hold the most promise of these natural retinoids in being biologically active,[11,35] provided the stability of the compound can be maintained with a proper formulation. When the sun-protected skin of individuals older than 80 years of age was treated for 7 days with 1 percent retinol, fibroblast growth and dermal collagen were increased significantly.[36] Concomitantly, retinol markedly reduced the levels of matrix-degrading metalloproteinases that are elevated in aged skin. These findings suggest that retinol may reverse and partially prevent skin atrophy that accompanies intrinsic aging. A recent clinical study has confirmed that topical retinol improves the fine wrinkles associated with atrophic, naturally aged skin of the elderly[37] (see Chap. 108).

ADVERSE EFFECTS

By far the most common adverse effect associated with topical retinoid use is local skin irritation characterized by erythema, peeling, dryness, tightness, and burning sensation. This predictable skin response is temporary, but troubling, for many patients. It tends to peak within the first month of treatment and diminishes thereafter. It responds to a temporary reduction in the frequency or amount of retinoid application and to liberal use of emollients. The requirement for RAR/RXR receptors in retinoid stimulation of basal keratinocyte proliferation was presented in Retinoid Target Genes and Their Activation Cascade in Human Skin. Retinoid activation of the receptors is followed by subsequent induction of HB-EGF and AR in human skin in vivo[18,19] (see Fig. 217-3). The importance of this signaling pathway in the hyperplastic response of the epidermis to topical retinoids was recently demonstrated when pharmacologic antagonists of EGF receptor tyrosine kinase activity blocked retinoid-induced epidermal thickening in human skin organ culture and in vivo.[18,19] This observation suggests that it may be possible to reduce the clinically undesirable effects of retinoids on epidermal keratinocytes. However, the erythema response following topical retinoic acid may not be retinoid-receptor mediated because all-*trans* retinol, which induces epidermal hyperpla-

sia and CRABP-II mRNA-like retinoic acid (two indicators of receptor activation), is minimally associated with clinical erythema.[11]

Systemic retinoid exposure has been well documented and established as a cause of embryonic death and congenital malformation, and understandably, there is concern about potential teratogenicity from long-term topical retinoid use. Systemic absorption of retinoids from topical application is negligible, and the levels of endogenous retinoic acid in the blood are not increased by twice daily application of 0.025 percent tretinoin to more than 40 percent of body area over 1 month. Furthermore, controlled topical administration of tretinoin at doses used for acne therapy (2 g of 0.025 percent gel applied daily to the face, neck, and upper part of the chest for 14 days) has less influence on plasma levels of endogenous retinoids than diurnal and nutritional factors.[38] Indeed, a large, population-based study demonstrated no excess risk of birth defects in offspring born to mothers who were exposed to topical tretinoin during pregnancy.[39] Therefore, no evidence exists for teratogenicity of topical tretinoin in humans. As mentioned in Hydroxylation of All-*Trans* Retinoic Acid, topical use of tretinoin induces in the skin the enzyme CYP26 that inactivates tretinoin. The induction of this enzyme would serve as a protective mechanism to partially reduce the amount of tretinoin for systemic absorption. In this regard, topical use of natural retinoids would be even safer than any of the synthetic compounds, because there already exists self-inducible enzymatic machinery that will inactivate excess tretinoin, but not synthetic retinoids.

"Sun sensitivity" is a frequently discussed subject with topical retinoid use and requires clarification. When formally tested in humans, topical tretinoin does not lower the minimal erythema dose of UVB light.[40] Because its presence in human skin does not increase the likelihood of sunburn reaction, tretinoin is not a phototoxic agent. When one talks to patients who complain of such sun sensitivity, they describe an uncomfortable skin sensation that is felt within minutes of being in the sun rather than hours later. This time line is not consistent with a typical sunburn reaction, which takes longer to be noticed (a few hours). Furthermore, this sensation is often said to be accentuated in warmer temperatures, which suggests participation of infrared irradiation (heat).

Related to sun sensitivity is the issue of photocarcinogenesis. In an animal model of photocarcinogenesis, topical tretinoin has caused skin cancer. However, this seems to be restricted to susceptible animals under contrived experimental conditions, and no evidence exists of a comparable process in humans. Indeed, by using a model in which human skin was grafted onto mice with severe combined immunodeficiency disease, gross inadequacy of the commonly used rodent model of photocarcinogenesis was demonstrated.[41] Specifically, the traditional rodent models significantly overestimate the human carcinogenic potential of tested agents. Topical retinoids, on the contrary, appear to have a protective effect against UV-induced premalignant and malignant lesions. In those predisposed by nevoid basal cell carcinoma syndrome or xeroderma pigmentosum to the development of nonmelanoma skin cancer, systemic retinoids have provided effective protection. In this regard, topical tretinoin's ability to prevent UV induction of c-Jun is relevant.[42] c-Jun is a proto-oncoprotein that is minimally detectable in normal human skin in vivo. Its partner c-Fos; however, is constitutively expressed. UV irradiation to human skin does not affect the level of c-Fos expression, but it markedly induces c-Jun protein, which can then heterodimerize with c-Fos, forming a complete active AP-1 transcription factor.[42] The critical importance of AP-1 in mediating carcinogenic transformation of papillomas has been demonstrated.[43] In human squamous cell carcinomas, c-Jun expression is elevated, and systemic retinoids prevent carcinomas of the head and neck. Mechanisms involved in this chemopreventive effect of the retinoid likely include c-Jun suppression. These clinically observed anticarcinogenic activities of retinoids are also supported by in vitro data, demonstrating that tretinoin treatment of human skin upregulates the antigen-presenting activity of Langerhans cells without concomitant increase in autoreactivity.[44] Such a retinoid effect would improve cutaneous immune responsiveness to tumor antigens. Therefore, topical retinoic acid is not a carcinogen in humans.

DRUG INTERACTION AND INCOMPATIBILITIES

Retinoids, in general, are photolabile and therefore can be photoinactivated. Based on this chemistry, it is prudent to apply the agents in the evening rather than before the start of the day. Because the major avenue of tretinoin inactivation is through CYP26, drugs that modulate the activity of this enzyme can potentially cause drug interactions. Ketoconazole and liarozole are effective inhibitors of CYP26 and, therefore, are RAMBAs.[15,23] Concurrent use of these azoles and topical tretinoin can increase the amount and prolong the half-life of tretinoin locally in the skin, thereby aggravating local side effect. Indeed, this was observed in one topical tretinoin study when a patient inadvertently started oral ketoconazole for tinea infection and experienced a severe and prolonged dermatitis, which could be reproduced by ketoconazole challenge. Other than retinoids, no other compounds have been shown to induce CYP26.

The use of vitamin D_3 and its analogues has increased in dermatology, and in particular for psoriasis (see Chap. 18). Vitamin D effects in human skin are largely mediated via its nuclear receptor VDR. As previously discussed in Retinoid Receptors, VDR is a member of the steroid/retinoic acid/thyroid hormone receptor superfamily. Like RAR, VDR functions in human skin mainly as a heterodimer with RXR (VDR-RXR). In contrast with retinoid signaling via RAR-RXR, in which the presence of RXR-ligand confers no additional effect, RXR-ligand provides a synergistic effect with VDR-ligand in vitamin D signaling.[45] Therefore, topical retinoids that possess, or through metabolic conversion, acquire RXR selectivity can positively influence vitamin D pharmacology in human skin.

CHAPTER 218

Topical Antibiotics

Mark W. Bonner
Paul M. Benson
William D. James

Topical antibiotics play an important role in the management of many common dermatologic conditions (Table 218-1). They are prescribed most often by dermatologists for the management of mild to moderate acne vulgaris or as adjunctive treatment with oral agents. For localized superficial infections, such as impetigo, the use of a topical agent (e.g., mupirocin) may eliminate the need for oral antibiotics and the accompanying problems of compliance, gastrointestinal side effects, and potential drug interactions. Topical antibiotics are still frequently prescribed as prophylactic agents after minor surgery or cosmetic procedures (chemical peel or laser resurfacing) to reduce the risk of postoperative wound infection and to speed wound healing. The use of topical antibiotics for prophylaxis after such minor procedures has been proven to be unnecessary and incurs risk of inducing allergy. Petrolatum is recommended for use after clean surgical procedures.

TOPICAL ANTIBIOTICS AT A GLANCE

- Topical antibiotics are useful in the treatment of acne and rosacea.
- Use in impetigo may obviate the need for oral antibiotics.
- Use of topical antibiotics to prevent wound infection after clean surgical procedures is unnecessary.

AGENTS USED IN THE TOPICAL TREATMENT OF ACNE AND ROSACEA

The efficacy of topical antibiotics for the treatment of acne vulgaris and rosacea may be due to their direct antibiotic effect, but many of the topical antibiotics exhibit anti-inflammatory properties by suppressing neutrophil chemotactic factor or by other mechanisms.[1] There are concerns about the use of topical antibiotics in the treatment of acne vulgaris because of the increasing levels of antibiotic resistance to common topicals. Combining the antimicrobial benzoyl peroxide with antibiotics reduces the development of antibiotic resistance.

Erythromycin

Erythromycin belongs to the group of macrolide antibiotics and is active against both Gram-positive cocci and Gram-negative bacilli. It is used princi-

TABLE 218-1
Topical Antibiotics

C = cream; EF-G = elongation factor G; G = gel; Gr + = Gram-positive; Gr – = Gram-negative; Gr ± = Gram-positive or -negative; L = lotion; NA = not available in the United States; O = ointment; P = pledget; S = solution.
[a]Bacteria refers to bacteria usually susceptible to antibiotic.
[b]Semisynthetic from chlortetracycline, fermented from some species of *Streptomyces*.
[c]Semisynthetic from tetracycline.
[d]Now completely synthesized.

pally as a topical agent in the treatment of acne. Erythromycin binds to the bacterial 50S ribosome and blocks translocation of the peptidyl-transfer RNA (tRNA) molecule from the acceptor to the donor site, interfering with the formation of the polypeptide chain and inhibiting protein synthesis. In addition to its antibacterial properties, erythromycin has anti-inflammatory activity.

Erythromycin is available as a 1.5 percent to 2.0 percent solution, gel, pledgets, and ointment as a single agent. It is also available in combination with benzoyl peroxide.

Clindamycin

Clindamycin is a semisynthetic lincosamide antibiotic that is derived from lincomycin. The mechanism of action is very similar to that of erythromycin, with binding to the 50S ribosome and suppression of bacterial protein synthesis. Clindamycin is used topically as a 1 percent gel, solution, suspension (lotion), and foam primarily for the treatment of acne. It is also available as a combination with benzoyl peroxide, which may slow the development of antibiotic resistance to clindamycin. Pseudomembranous colitis rarely has been reported to occur with the topical use of clindamycin.[2]

Metronidazole

Metronidazole, a topical nitroimidazole, is currently available as a 0.75 percent gel, cream, or lotion and as a 1 percent cream or gel for the topical treatment of rosacea. In the lower strength, it is applied twice daily, and in the higher strength, it is used once daily. Orally, metronidazole has broad-spectrum activity against many protozoal organisms and anaerobes.

Azelaic Acid

Azelaic acid is a dicarboxylic acid found in food (whole-grain cereals and animal products). There is a normal human plasma level (20 to 80 ng/mL); topical application does not significantly alter this level. The mechanism of action is thought to be normalization of the keratinization process (decreased thickness of the stratum corneum, decreased number and size of keratohyaline granules, and decreased amount of filaggrin). There are reports of in vitro activity against *Propionibacterium acnes* and *Staphylococcus epidermidis*, which may be due to protein synthesis inhibition. In aerobic microorganisms, there is inhibition of oxidoreductive enzymes (such as tyrosinase, mitochondrial enzymes of the respiratory chain, 5α-reductase, and DNA polymerases). In anaerobic bacteria, there is disruption of glycolysis. Azelaic acid is used principally in the treatment of acne vulgaris and rosacea, although there are some advocates for its use in the treatment of hyperpigmentation (such as melasma for which it was initially developed). However, the U.S. Food and Drug Administration has not approved the drug for this indication. Azelaic acid is available as a 15 percent gel or 20 percent cream preparation.

Sulfonamides (Sulfacetamide)

Sulfacetamide is a topical sulfonamide used in the treatment of rosacea and acne. The antibacterial mechanism of action for most sulfonamides is competition with para-aminobenzoic acid (PABA) during the synthesis of folic acid. The mechanism of action for topical treatment of rosacea is not understood at this time. Sulfacetamide is available as a 10 percent lotion and in combination with 5 percent sulfur in a gel, cream, suspension, cleanser, cloths, and mask.

AGENTS USED FOR THE TOPICAL THERAPY OF SUPERFICIAL BACTERIAL INFECTIONS AND BURNS

Localized impetigo, superficial dirty abrasions, and secondarily infected chronic dermatoses are commonly treated with topical antibiotics. However, widespread impetigo, infection of the lower extremities, or disease occurring in immunocompromised individuals should be treated with systemic antibiotics to reduce the risk of serious complications. Topical antibiotics are still at times used following minor surgical procedures. The result of a large study comparing bacitracin and petrolatum in more than 1200 minor surgical procedures demonstrated that bacitracin did not statistically decrease the already low rate of infection. Several patients were, however, shown to be allergic to bacitracin. Petrolatum proved to be cheaper, of equal efficacy and to have fewer side effects than bacitracin.[3] When clean wounds are made during minor surgery, there is no need to use antibacterial ointment to aid in healing or prevent infection. Because burns produce a fertile ground for life-threatening secondary infection, prophylactic topical therapy is often used.

Mupirocin

Mupirocin, which was formerly known as *pseudomonic acid A*, is a topical antibiotic agent derived from *Pseudomonas fluorescens*. The drug reversibly binds to isoleucyl-tRNA synthetase and inhibits bacterial protein synthesis. The activity of mupirocin is limited to Gram-positive bacteria, especially staphylococci and most streptococci. Its activity is enhanced in an acid pH environment (5.5), which is the normal pH of the skin. Mupirocin is somewhat temperature-sensitive, and thus loses efficacy if exposed to high temperatures. Mupirocin ointment 2 percent is applied three times daily and is principally indicated for the treatment of localized impetigo caused by *S. aureus* and *Streptococcus pyogenes*. One study in the Tennessee Veterans' Affairs Hospital demonstrated that prolonged use of mupirocin ointment to control methicillin-resistant *S. aureus* (MRSA) carriage, especially in bedridden patients with decubitus ulcers, led to significant resistance.[4] Furthermore, Japanese researchers found that low serum concentrations of mupirocin are achieved after intranasal application and postulated that this might explain the selection of mupirocin-resistant strains of *S aureus*.[5] A small pilot study using intranasal application of a combination antibiotic ointment containing bacitracin, polymyxin B, and gramicidin successfully decolonized 80 percent (9 out of 11) of MRSA-positive patients who remained clear after a mean follow-up of 2 months. All cases of mupirocin-sensitive MRSA were eradicated, whereas only three of five cases of mupirocin-resistant were eliminated.[6] New formulations that involve the use of the calcium salt of mupirocin (the calcium salt aids in chemical stability in the intranasal preparation) are available for intranasal use as a 2 percent ointment and a 2 percent topical cream.

Bacitracin

Bacitracin is a topical polypeptide antibiotic originally isolated from the Tracy-I strain of *Bacillus subtilis*. Bacitracin is a cyclic polypeptide with multiple components (A, B, and C). Bacitracin A is the major component of commercial products and is often used as the zinc salt. Bacitracin interferes with bacterial cell wall

synthesis by binding to and inhibiting the dephosphorylation of a membrane-bound lipid pyrophosphate. It is active against Gram-positive cocci such as staphylococci and streptococci. Most Gram-negative organisms and yeast are resistant to the drug. It is available as bacitracin ointment and as zinc bacitracin, with 400 to 500 units per gram.

Topical bacitracin is effective for the treatment of superficial bacterial infections of the skin such as impetigo, furunculosis, and pyodermas. It is often combined with polymyxin B and neomycin as a triple antibiotic ointment applied several times daily for the treatment of secondarily infected eczematous dermatitis such as atopic dermatitis, nummular dermatitis, or stasis dermatitis. Unfortunately, the topical application of bacitracin carries with it the risk of allergic contact sensitization and, rarely, anaphylactic shock.[7]

Polymyxin B

Polymyxin B is a topical antibiotic derived from a spore-forming soil aerobe *B. polymyxa*. Polymyxin B is a mixture of polymyxin B_1 and B_2, which are both cyclic polypeptides. They function as cationic detergents that interact strongly with bacterial cell wall membrane phospholipids, thus disrupting the integrity of the cell membrane.

Polymyxin B is active against a wide range of Gram-negative organisms, including *P. aeruginosa*, *Enterobacter*, and *Escherichia coli*. Polymyxin B is available in ointment form (5000 to 10,000 units per gram) in combination with bacitracin or as triple antibiotic ointment with bacitracin and neomycin. It should be applied one to three times a day.

Topical Aminoglycosides (Neomycin and Gentamicin)

The aminoglycosides are an important group of antibiotics used both topically and systemically for the treatment of infections caused by Gram-negative bacilli. Aminoglycosides exert their bactericidal effects by binding to the 30S ribosomal subunit and interfering with protein synthesis.

Neomycin sulfate, the aminoglycoside most often used topically, is a fermentation product of *Streptomyces fradiae*. Commercial neomycin is a mixture of neomycin B and C, whereas framycetin, used in Canada and some European countries, is pure neomycin B.[8] Neomycin sulfate has activity against aerobic Gram-negative bacteria and is used most commonly for prophylaxis against infection in superficial abrasions, cuts, and burns. It is available in ointment form (3.5 mg/g) and is also packaged in combination with other antibiotics such as bacitracin, polymyxin, and gramicidin. Other agents, such as lidocaine, pramoxine, or hydrocortisone, also are available in combination with neomycin.

Neomycin is not recommended by many dermatologists because it is responsible for a large number of cases of allergic contact dermatitis. The prevalence of contact dermatitis is high, with 6 percent to 8 percent of patients undergoing patch testing being positive.[9] Neomycin sulfate (20 percent) in petrolatum is used to assess for contact allergy.

Gentamicin sulfate is derived as a fermentation product from *Micromonospora purpurea*. It is available as a topical 0.1 percent cream or ointment. It is used by some dermatologic surgeons when operating on the ear, especially in diabetic or other immunocompromised patients, to provide prophylaxis against malignant otitis externa due to *P. aeruginosa*. The ophthalmic formulation is useful in caring for operative wounds in the periorbital area.

Sulfonamides (Silver Sulfadiazine and Mafenide Acetate)

The sulfonamides are structurally similar to PABA and compete with it during the synthesis of folic acid. Sulfonamides are used to treat acne vulgaris, acne rosacea, and burns. Silver sulfadiazine is thought to release silver slowly and exerts its effect on the bacterial cell walls and membranes. The mechanism of action of mafenide is not the typical sulfonamide mechanism of action because PABA does not antagonize its performance. Mafenide acetate, if used over large areas of skin, has the potential to cause metabolic acidosis, and it can cause intense pain on topical administration. Both agents are broad-spectrum antibacterials useful in the treatment of burns. *Candida* superinfection may be a problem with mafenide cream.

Nitrofurazone

Nitrofurazone (Furacin) is a nitrofuran derivative used for the treatment of burn patients. The mechanism of action involves the inhibition of bacterial enzymes involved in the aerobic and anaerobic degradation of glucose and pyruvate. Nitrofurazone is available as a 0.2 percent cream, solution, or soluble dressing, and its spectrum of activity includes staphylococci, streptococci, *E. coli*, *Clostridium perfringens*, and *Proteus* sp.

MISCELLANEOUS AGENTS

Gramicidin

Gramicidin is a topical antibiotic derived from *B. brevis*. The gramicidins are linear peptides that form stationary ion channels in susceptible bacteria. The antibiotic activity of gramicidin is restricted to Gram-positive bacteria.

Chloramphenicol

Chloramphenicol is available in the United States with use limited to the treatment of minor bacterial skin infections. The mechanism of action is similar to that of erythromycin and clindamycin, with inhibition of the 50S ribosome blocking translocation of peptidyl tRNA from the acceptor to the donor site. Chloramphenicol is available as a 1 percent cream. It is used infrequently because fatal aplastic anemia or dose-related bone marrow suppression has been reported following topical exposure.[10]

Clioquinol

Clioquinol (also known as *iodochlorhydroxyquin*) is a broad-spectrum antibacterial/antifungal topical that is currently indicated for the treatment of inflammatory skin disorders and tinea pedis and has been used for minor bacterial infections. It is a synthetic hydroxyquinoline whose mechanism of action is unknown. The disadvantages of clioquinol include discoloration of clothing, skin, hair, and nails and the potential to cause irritation. Clioquinol may interfere with thyroid function determination because the iodine moiety interferes with tests that rely on iodine uptake (this effect can last for up to 3 months after application). However, clioquinol does not interfere with testing for T3 or T4.

CHAPTER 219

Topical Antifungal Agents

Whitney A. High
James E. Fitzpatrick

Superficial fungal infections, including dermatophytoses, candidiasis, and pityriasis versicolor, are most often restricted to the epidermis. In treating these infections, the clinician must select between topical or systemic management. Factors guiding management include, but are not limited to, the:

- extent and severity of the infection,
- site of involvement,
- co-morbid conditions or potential drug interactions, if any,
- anticipated efficacy of treatment,
- cost and access to medication, and
- ease of use.

Patients with limited fungal infections confined to glabrous skin are usually best treated with topical agents. Conversely, those with extensive or recalcitrant disease, or with involvement of terminal hair or nails, may be better suited for systemic management. In some cases, either treatment option may be reasonably chosen.

Treatment with topical antifungal therapy enjoys several advantages over systemic management, including:

- fewer side effects,
- fewer drug interactions,
- localization of treatment, and
- generally lower cost.

Numerous topical antifungal medications are available (Table 219-1). For the most part, specific antifungal agents have replaced non-specific topical treatments, such as keratolytics (salicylic acid) or antiseptics (gentian violet or Castellani's paint), which were once the cornerstones of management.

The "ideal" topical antifungal is easily defined (Table 219-2), yet no one current topical agent possesses all of these properties. Despite widespread availability, few topical antifungal agents have been directly compared with one another in clinical trials. Studies sponsored by the manufacturer often compare just the active agent to the vehicle. Extrapolation between studies is further complicated due to differences in study design, duration of therapy, site of infection, selection methodology, or treatment endpoint.

Most topical antifungals belong to one of three classes: (1) imidazoles, (2) allylamines and benzylamines, and (3) polyenes. Some agents do not fit well into this schema and are discussed separately.

IMIDAZOLES

Imidazoles represent a broad class of antifungal medications. Certain of these, such as clotrimazole, have been around for decades, while others, such as sertaconazole, have only become available recently.

Mechanism of Action

Imidazoles impede synthesis of a component of the fungal cell wall through inhibition of lanosterol 14α-demethylase, a cytochrome P_{450} dependent enzyme, which converts lanosterol to ergosterol.[1] Depletion of ergosterol results in membrane instability and hyperpermeability, which are changes incompatible with growth and survival of the fungus. Imidazoles are considered fungistatic. Although all possess the same mechanism of action, in vitro studies demonstrate that not all dermatophytes are uniformly susceptible to an imidazole at an equivalent concentration, and this may explain some treatment failures.[2–4] Currently, there is no uniform reference method for susceptibility testing of dermatophytes.

Topical imidazoles possess anti-inflammatory activity via inhibition of neutrophil chemotaxis, calmodulin activity, synthesis of leukotrienes and prostaglandins, and histamine release from mast cells.[5–7] Some agents, such as ketoconazole, yield anti-inflammatory effects equivalent to 1 percent hydrocortisone.[8] Topical imidazoles also demonstrate limited antibacterial properties, particularly with respect to Gram-positive organisms.[9,10]

TOPICAL ANTIFUNGAL AGENTS AT A GLANCE

- Preferred treatment for superficial fungal infection of limited extent.
- Low cost, low incidence of drug interactions, few side effects and complications, ease of use.
- Use systemic agent when superficial fungal infection affects large surface area, involves terminal hair or nails, or is resistant to topical management.
- Topical antifungal classes: Imidazoles, allylamines, benzylamines, polyenes.
- Ciclopirox olamine: Unique topical antifungal with broad-spectrum activity, variety of indications.
- Side effects: Irritant dermatitis, allergic contact dermatitis, urticarial reactions.
- Combination agents (antifungal and steroid): Watch for side effects due to glucocorticoids.
- Combination agents: Higher rate of treatment failure, disease relapse.

TABLE 219-1
Topical Antifungal Agents Commonly Used in Dermatology

Generic Name(s)	Trade Name(s)	Formulation	Pregnancy Class	Rx/OTC
Imidazoles				
Clotrimazole	Cruex (Rx) Desenex AF Lotrimin Lotrimin AF Mycelex	1% cream, lotion, lozenges/troches, powder, spray solution, solution	C	Rx and OTC
Econazole	Spectazole Ecostatin	1% cream	C	Rx only
Ketoconazole	Nizoral Nizoral AD	1% and 2% cream and shampoo	C	Rx and OTC
Miconazole	Micatin Micozole Monistat-Derm Zeasorb AF	2% cream, lotion, powder, spray powder, spray solution	C	OTC
Oxiconazole	Derimine Myfungar Oceral Oceral GB Okinazole Oxistat Oxizole	1% cream, lotion	B	Rx
Sertaconazole	Ertaczo	2% cream	C	Rx
Sulconazole	Exelderm Sulcosyn	1% cream, solution	C	Rx
Allylamines				
Naftifine	Naftin	1% cream, gel	B	Rx
Terbinafine	Lamisil Lamisil AT	1% cream, spray solution, solution	B	Rx
Benzylamines				
Butenafine	Mentax	1% cream	B	Rx
Polyenes				
Nystatin	Bio-Statin Mycostatin Nystop Pedi-Dri	100,000 U/g cream, lozenge/troche, ointment, powder, solution	C[a]	Rx
Other topical antifungals				
Ciclopirox olamine	Loprox Penlac	0.77% cream or lotion, 1% shampoo or solution, 8% nail lacquer	B	Rx
Tolnaftate	Equate (Wal-Mart) Tinactin	1% cream, powder, spray powder, spray solution, solution	N/A	OTC
Undecylenic acid	Desenex[b] Cruex (OTC)[c]	20% cream, 10% penetrating foam, 10%–20% powder, 20% spray powder	N/A	OTC
Combination agents				
Clotrimazole-betamethasone dipropionate	Lotrisone	1% clotrimazole and 0.05% betamethasone dipropionate in cream or lotion	N/A	Rx
Nystatin-triamcinolone acetonide	Mycolog-II Mytrex Quenalog	100,000 U/g nystatin and 0.1% triamcinolone acetonide	N/A	Rx

N/A = not applicable; OTC = over-the-counter agent; Rx = prescription agent.
[a]Varying pregnancy class depends on form; majority of forms are Category C.
[b]Some forms of Desenex contain other agents, such as tolnaftate, clotrimazole, miconazole, or terbinafine.
[c]Some forms of Cruex contain miconazole.

TABLE 219-2
Properties of an Ideal Topical Antifungal Agent

- Broad spectrum of action
- Fungicidal at therapeutic concentration
- Absence of resistance within the targeted fungi
- Keratinophilic with penetration of the cornified envelope without systemic absorption
- Nonirritating and hypo-allergenic
- Possess anti-inflammatory properties
- Once-per-day application (or less)
- Short duration of therapy for cure
- Availability in multiple formulations (cream, solution, etc.) and sizes
- Inexpensive

Pharmacokinetics

Topical antifungals are designed expressly for treating superficial fungal infections. Consequently, all marketed imidazoles demonstrate excellent penetration of the stratum corneum with strong keratinophilic behavior. Sulconazole may be detected in the stratum corneum up to 96 hours after application.[11] Similarly, sertaconazole, the newest of all marketed imidazoles, has a half-life within the stratum corneum of more than 60 hours.[12] Because of this high affinity for keratin, systemic absorption of imidazoles is low, with urinary excretion usually in the range of 0.3 percent to 1.0 percent of the applied dose. Even when applied to inflamed skin, absorption of imidazoles does not usually exceed 4 percent of the applied dose. Again, sulconazole is unique in that percutaneous absorption in the range of 8 percent to 11 percent of the applied dose exceeds that of all other imidazoles.[11]

Indications

Indications for topical imidazole use are detailed in Table 219-3. Because of inherent antibacterial activity, some topical imidazoles have demonstrated modest efficacy in treating erythrasma, impetigo, and ecthyma. Because there are more potent antibacterial agents, this is *not* a preferred indication for imidazole use.[8,13,14]

Cure rates for superficial fungal infection treated with imidazoles are variable and often depend upon study design. For example, topical miconazole has demonstrated a 63 percent to 100 percent cure rate, depending upon the study quoted. A thorough review of the literature provides no compelling evidence that significant differences in cure or relapse exist among the various topical imidazoles; however, other considerations may dictate selection of a particular imidazole.

TABLE 219-3
Indications for the Use of Topical Imidazoles

- Dermatophytoses
  - Tinea pedis/tinea manum
  - Tinea cruris
  - Tinea corporis
  - Tinea faciei (the unbearded face)
- Pityriasis versicolor
- Mucocutaneous candidiasis[a]
  - Cutaneous candidiasis
  - Vulvovaginal candidiasis[b]
  - Oral candidiasis (thrush)[c]
  - Perlèche
- Seborrheic dermatitis[d]

[a]Oxiconazole and sulconazole have relatively weaker activity against *Candida*.
[b]Clotrimazole, econazole, miconazole, terconazole, and tioconazole are available as vaginal preparations.
[c]Clotrimazole-dissolving troches are used for oral thrush.
[d]Ketoconazole is used for seborrheic dermatitis.

Topical imidazoles are available as a cream or lotion. Although lotions are better suited for use over large areas or upon hair-bearing skin, limited studies suggest a cream may be marginally more effective. In studies performed by the manufacturer, oxiconazole cream yielded a clinical and mycologic cure in 52 percent of tinea pedis cases while the lotion yielded the same cure in just 41 percent of cases. Additionally, the potential for irritancy must be considered. In one study of topical clotrimazole for treatment of tinea cruris, erosive reactions developed in four of 27 patients while sulconazole did not cause any erosions in the same population.[15] Similarly, in a second study, severe irritant reactions were reported with miconazole use but not with sulconazole use.[16] Until formal studies of irritancy are performed we often recommend use of sulconazole in sensitive areas such as the groin. Finally, ease of use may be a factor to consider, as some imidazoles are specifically approved for once-daily dosing (see Dosing Regimen).

Dosing Regimen

Topical imidazoles are available in a multitude of forms (see Table 219-1). Econazole, ketoconazole, and oxiconazole are approved for once-daily dosing but twice-daily dosing is recommended for the remainder. Nevertheless, although twice-daily dosing is recommended for sulconazole, a study comparing once-daily to twice-daily dosing in tinea corporis and tinea cruris reported an identical rate of cure.[15] This might have been predicted based upon the 60-hour half-life within the stratum corneum.[12] Application of all topical antifungals, including imidazoles, should include normal skin for a radius of 2 cm beyond the affected area. Duration of treatment with imidazoles has varied. In general, tinea corporis and tinea cruris require treatment for approximately 2 weeks, whereas tinea pedis may require treatment for up to 4 weeks.[17] Treatment should be continued for at least 1 week after all symptoms have abated.[18]

Risks and Precautions

Risks associated with the use of topical imidazoles include those inherent to all topical medications (Table 219-4). Additionally, clotrimazole is marketed in combination with the topical glucocorticoid, betamethasone dipropionate. It was assumed that the addition of the steroid would more rapidly relieve inflammation, scaling, and pruritus. Early studies demonstrated the combination was indeed more effective than clotrimazole alone in alleviating symptoms.[19,20] However, betamethasone dipropionate is a potent topical steroid and, soon after release of the combination product, striae and other cutaneous side effects from the steroid component were reported.[21] Longer-term studies also reported a higher relapse rate (36 percent) with use of combination product.[22,23]

This combination product may comprise 50 percent or more of antifungal prescriptions by primary care providers, compared to less than 7 percent among dermatologists.[24] It is likely that overuse by non-specialists occurs because of the mistaken assumption either that the steroid agent is mild, or that the combination will be a "better choice" when the differential diagnosis is unresolved.[25] The U.S. Food and Drug Administration has twice

TABLE 219-4
Adverse Reactions to Topical Antifungals

- Irritant contact dermatitis (worsened by occlusion)
- Allergic contact dermatitis (to active agent or more likely to other ingredients/preservatives)
- Urticarial reactions (rare)
- Inappropriate treatment due to misdiagnosis (more likely with over-the-counter agents)

revised the product warnings for clotrimazole-betamethasone dipropionate, discouraging use on thin skin, for prolonged periods, or when the diagnosis is in doubt.

Complications

Use of topical imidazoles is associated with few complications. Because of low systemic absorption, drug interactions with topical imidazoles are extremely rare. Nevertheless, in a single study, increased serum tacrolimus levels were observed in renal transplant recipients who used clotrimazole troches for mucocutaneous candidiasis.[26] For this reason, use of nystatin may be preferred when treating thrush in transplant patients using tacrolimus.

Concerns of resistance must also be considered. Resistance of *Candida albicans* to clotrimazole has been described in human immunodeficiency virus-positive patients with mucocutaneous candidiasis.[27] Low levels of in vitro resistance of various *Candida* sp. to other topical imidazoles has also been documented.[28] Often, this resistance is associated with resistance to oral fluconazole.

ALLYLAMINES AND BENZYLAMINES

Allylamines and benzylamines are closely related compounds. Currently, two topical allylamines and a single topical benzylamine are marketed (see Table 219-1).

Mechanism of Action

Allylamines and benzylamines share a common mechanism of action. These agents impede synthesis of ergosterol through inhibition of squalene epoxidase, an enzyme that converts squalene to squalene oxide.[29] Depletion of ergosterol results in membrane instability and hyperpermeability. Allylamines and benzylamines are considered fungicidal because the accumulation of intracellular squalene leads directly to cell death. The clinical significance of this cidal action is unclear. Unlike imidazoles, the activity of allylamines and benzylamines is independent of the cytochrome P_{450} enzyme system. When compared to naftifine, terbinafine demonstrates a 10- to 100-fold increased potency in vitro, although this does not appear to be relevant in clinical use.

Like imidazoles, allylamines and benzylamines demonstrate anti-inflammatory activity.[5,30] Naftifine inhibits adhesion of polymorphonuclear cells to endothelium, interrupts chemotaxis, and inhibits the 5-lipoxygenase pro-inflammatory pathway.[31,32] It is assumed that terbinafine and butenafine yield anti-inflammatory effects through similar mechanisms. Allylamines and benzylamines also demonstrate limited antibacterial properties. In fact, a recent study showed lowered minimum inhibitory concentrations for bacteria as well as fungi when terbinafine was used in combination with benzoyl peroxide.[33]

Pharmacokinetics

Allylamines and benzylamines are highly lipid soluble and efficiently penetrate the stratum corneum, where they may persist for extended durations.[34] Butenafine has been detected within the stratum corneum at minimum inhibitory concentration for at least 72 hours after application,[35] and terbinafine may persist at a similar level for up to 7 days after application.[36] Systemic absorption of these agents is quite low, with typical urinary excretion in the range of 3 percent to 5 percent of the applied dose, an amount considered biologically and clinically insignificant.[36]

Indications

Indications for the use of topical allylamines and topical benzylamines are detailed in Table 219-5. Despite antibacterial properties, terbinafine has proven inferior to mupirocin for treatment of impetigo,[37] and a traditional antibacterial agent should be used instead. Similarly, although allylamines and benzylamines do demonstrate activity against dimorphic fungi involved in systemic infection such as *Sporothrix schenckii*, *Blastomyces dermatitidis*, and *Histoplasmosis capsulatum*, topical therapy is inappropriate in this situation.

Limited evidence suggests that topical allylamines or benzylamines may be preferred over topical imidazoles for certain dermatophyte infections. Repeated trials for tinea pedis indicate that 1 week of topical terbinafine is as effective as 4 weeks of topical imidazoles, with cure resulting in 53 percent to 95 percent of cases.[38–41] Use of this abbreviated treatment with terbinafine has been confirmed in trials using the active agent versus vehicle alone.[42] In some instances, resolution of tinea pedis using terbinafine has occurred with as few as three doses.[43]

Currently a 30-g tube of terbinafine is three times more expensive than a 30-g tube of clotrimazole.[44] Considering the frequency of application, the amount of medication required, the likelihood of patient compliance and ease of use, and the rapidity of results, some experts recommend topical terbinafine over topical imidazoles for tinea pedis.[45,46] Nevertheless, using the same data, other experts have recommended initial use of less expensive imidazole therapy with reservation of allylamines and benzylamines for treatment failure.[47] A consensus has not yet been achieved.

Finally, topical allylamines and benzylamines are effective against *Candida* or *Pityrosporum* sp. However, given the relative cost of these agents compared to cheaper, equally reliable, and specifically approved agents, such as imidazoles, polyenes, ciclopiroxamine, and over-the-counter selenium sulfide, there is no compelling reason to turn away from these more affordable options.

TABLE 219-5
Indications for the Use of Topical Allylamines and Benzylamines

- Dermatophytoses
  - Tinea pedis/tinea manum
  - Tinea cruris
  - Tinea corporis
  - Tinea faciei (the unbearded face)
- Pityriasis versicolor[a]

[a]Although butenafine is approved by the U.S. Food and Drug Administration for use in pityriasis versicolor, the availability of numerous, more cost-effective remedies limits use in this clinical situation.

Dosing Regimen

Topical allylamines and benzylamines are available in a number of forms (see Table 219-1). Each agent has a slightly different dosing regimen based upon the formulation and the location and severity of infection (Table 219-6).

Risks and Precautions

Risks associated with use of topical allylamines and benzylamines are those inherent to all topical medicaments (see Table 219-3).

Complications

Complications occurring with use of topical allylamines or benzylamines are few.

POLYENES

Polyenes were among the first agents discovered to possess specific antifungal

TABLE 219-6
Recommended Use of Topical Allylamines and Benzylamines

	Recommendations	
Agent	Frequency of Application	Duration of Application
Naftifine	Cream—once daily Gel—twice daily	General instructions for use 2 wk beyond resolution of symptoms
Terbinafine	Tinea pedis (interdigital)—twice daily Tinea pedis (plantar)—twice daily Tinea elsewhere—once or twice daily	At least 1 wk At least 2 wk At least 1 wk, up to 4 wk
Butenafine	Tinea pedis—once to twice daily Tinea elsewhere—once daily Pityriasis versicolor—once daily[a]	At least 1 wk if twice daily, and at least 4 wk if once daily At least 2 wk At least 2 wk

[a]Although butenafine is approved by the U.S. Food and Drug Administration for use in pityriasis versicolor, the availability of numerous, more cost-effective remedies limits use in this clinical situation.

properties. The two major topical polyene antifungals are nystatin and amphotericin B. Only topical nystatin is actively marketed in the United States (see Table 219-1).

Mechanism of Action

Like all polyenes, nystatin binds irreversibly to membrane sterols present in susceptible species of *Candida*.[48] The polyene molecules demonstrate a higher affinity for fungal sterols, including ergosterol, than for human sterols, yielding imperfect selective toxicity. This irreversible binding alters membrane permeability, causing leakage of essential intracellular components and fungal death. In low concentrations, nystatin is fungistatic, but at high concentrations it may be fungicidal.[49]

Pharmacokinetics

Nystatin is insoluble in water and is not absorbed from intact skin, the gastrointestinal tract, or the vagina.[50]

Indications

Topical nystatin is used to treat mucocutaneous candidiasis caused by *C. albicans*, and other susceptible species such as *C. parapsilosis*, *C. krusei*, and *C. tropicalis*. Repeated studies have demonstrated that topical imidazoles are more effective than nystatin in treating vulvovaginal candidiasis, and use of nystatin for this indication has diminished in recent years.[51,52] Nystatin is not effective against dermatophytes or *Pityrosporum*; and hence, it is not indicated for treatment of tinea or pityriasis versicolor.

Dosing Regimen

Nystatin is available as a powder, cream, ointment, suspension, and pastille. To treat oral candidiasis (thrush), the suspension or pastille is used four to five times daily, usually for 2 weeks. To treat cutaneous infection, the powder, cream, and ointment are used twice daily for approximately 2 weeks.

Risks and Precautions

Risks associated with use of topical nystatin are those inherent to all topical medicaments (see Table 219-3). A significant number of cases of allergic contact dermatitis attributed to nystatin alone have been reported. These reactions have been reported with topical and oral use.[53,54] Anaphylaxis has been described with use of nystatin-containing vaginal suppositories but the reaction was attributed to ingredients other than nystatin.[55]

A combination agent consisting of nystatin and triamcinolone acetonide is widely marketed. The addition of triamcinolone may provide additional benefit over nystatin alone during the first few days of treatment when inflammation is maximal.[56] After this initial period, the manufacturer recommends a transition to nystatin alone or to other topical antifungal agents. Although triamcinolone acetonide is only a mid-potency agent, cutaneous sequelae, including striae, skin atrophy, and steroid-induced acne, have been reported.[57] Because candidiasis often involves thin and fragile skin, such as that of the intertriginous areas, the risk of damage is likely potentiated. Finally, many of the combined formulations contained, or may still contain, ethylenediamine, a sensitizer that may cause allergic contact dermatitis.[58] As with clotrimazole-betamethasone dipropionate, the combination agent of nystatin-triamcinolone acetonide is more often prescribed by non-dermatologists.

Complications

Complications with topical polyenes are few. Nystatin resistance may be encountered in some *Candida* sp.[59,60] This resistance may either be seen in wild strains (primary-type) or it may be induced during therapy (secondary-type). Although *C. albicans* maintains a low rate of spontaneous resistance to nystatin,[61] particularly in comparison to resistance to imidazoles,[62] other species, such as *C. tropicalis*, *C. guilliermondi*, *C. krusei*, and *C. stellatoides*, rapidly acquire resistance upon exposure to nystatin.

OTHER AGENTS

Some topical antifungals, such as ciclopirox olamine, tolnaftate, and undecylenic acid, do not fit well into the major classes and are instead discussed separately.

Ciclopirox Olamine

Ciclopirox olamine is a hydroxypyridone antifungal agent with a unique structure and mode of action.

MECHANISM OF ACTION Unlike most other topical antifungals, ciclopirox olamine does not interfere with sterol synthesis.[63] Instead, it interrupts active membrane transport of essential cellular precursors, particularly trivalent cations.[64] Ultimately, this disrupts cellular function, leading to demise of the fungus. If concentrations of the drug are high enough, the membrane integrity of the fungus may actually be impaired.

Ciclopirox olamine also has inherent anti-inflammatory activity exerted through inhibition of prostaglandin and leukotriene synthesis within polymorphonuclear cells.[65] Broad-spectrum antibacterial properties have also been attributed to ciclopirox olamine. In one study, topical ciclopirox olamine had broader coverage against Gram-positive and Gram-negative organisms than did topical imidazoles or topical allylamines.[66]

PHARMACOKINETICS When applied to the skin, ciclopirox olamine remains in high concentration within the epidermis

and upper dermis. Ciclopirox olamine penetrates keratin easily, with cadaveric skin demonstrating concentrations in the epidermis that were 10 to 15 times the minimum inhibitory concentration for a sensitive species.[65] This ability to penetrate keratin recommends use for onychomycosis, as the drug is also capable of penetrating the nail plate material.[67] Studies of drug metabolism have demonstrated that, with typical use, approximately 10 percent of the administered dose is excreted in the urine.[68]

INDICATIONS Ciclopirox olamine is indicated for the treatment of dermatophytoses and onychomycosis, candidiasis, pityriasis versicolor, seborrheic dermatitis, and even cutaneous infections with unusual saprophytes.[69] In tinea pedis, a mycologic cure rate of up to 85 percent has been observed, and in seborrheic dermatitis, a significantly larger percentage of users had > 75 percent improvement with 2 weeks of use than those using the shampoo vehicle alone.[70,71]

Although treatment with ciclopirox olamine for tinea pedis and seborrheic dermatitis has yielded results on par with other modalities, use in onychomycosis has met with more modest success. Often, an assessment of efficacy depends upon whether a mycologic cure (culture-negative) or clinical cure (a disease-free nail) defines success.[72] Although a disease-free nail is often the patient's true goal, ciclopirox olamine achieved such a response in just 5.5 percent to 8.5 percent of those treated with a standard 48-week course.[72,73] Two recent trials demonstrated increased efficacy when using oral terbinafine in combination with topical ciclopirox olamine, as opposed to oral terbinafine alone.[74,75] Debate regarding the use of ciclopirox olamine as an independent or adjunct treatment for onychomycosis is ongoing.

DOSING REGIMEN Ciclopirox olamine is available in a wide range of forms (see Table 219-1). Cutaneous candidiasis, dermatophytoses, and pityriasis versicolor should be treated twice daily for 2 weeks to 1 month, but treatment for tinea pedis should continue 1 month or longer. When using ciclopirox shampoo for seborrheic dermatitis, treatment may occur twice weekly for an indefinite duration. Improvement is generally noted in 2 to 4 weeks. Finally, in treating onychomycosis, the nail lacquer is applied daily to the nail and hyponychium for 48 weeks and excess medication is removed weekly with alcohol.

RISKS AND PRECAUTIONS Risks associated with use of topical ciclopirox olamine are those inherent to all topical medicaments (see Table 219-3). Allergic contact dermatitis has been reported only rarely, and ciclopirox olamine is considered a weak sensitizer.[76] In patients with an allergic reaction to ciclopirox, imidazoles may be used with relative safety because of a markedly different chemical structure.

COMPLICATIONS Serious complications with topical ciclopirox olamine are few.

Older Agents

Tolnaftate and undecylenic acid are older agents now available only in over-the-counter products (see Table 219-1). Repeated studies have now demonstrated that they are approximately equal in efficacy,[77,78] and that both are less efficacious than topical imidazoles, allylamines, benzylamines, and ciclopirox olamine. Additionally, tolnaftate is ineffective for treating candidiasis. Topical tolnaftate and topical undecylenic acid share the same risks and precautions inherent to all topical medications (see Table 219-3). Additionally, topical forms of undecylenic acid may yield an unpleasant "fishy smell" that further discourages use. Because both agents are considered less efficacious than imidazoles, monitoring for treatment failure is indicated when using these medications.

TOLNAFTATE

UNDECYLENIC ACID

CONCLUSIONS

Because of relatively low cost, acceptable efficacy, ease of use, and low potential for side effects, complications, or drug interactions, topical antifungals are preferred for most superficial fungal infections of limited extent. Alternatively, use of a systemic agent is justified when a superficial fungal infection covers a large surface area, involves terminal hair or nails, or has proven recalcitrant to prior topical management. Imidazoles provide a reasonable balance of efficacy and affordability and are indicated for treatment of dermatophytoses, mucocutaneous candidiasis, and pityriasis versicolor. Despite higher cost, allylamines and benzylamines may be advantageous in some cases of tinea pedis, due to shorter treatment courses. Ciclopirox olamine is a topical antifungal with a unique mechanism of action and a broad range of indications. Topical nystatin is useful in treating mucocutaneous candidiasis, but is ineffective for dermatophyte infections. Use of tolnaftate and undecylenic acid is decreasing due to lower efficacy compared with other available agents.

CHAPTER 220

Topical and Intralesional Cytotoxic Agents

Megan M. Moore
Bruce E. Strober

5-FLUOROURACIL

Mechanism of Action and Formulations

Topical 5-fluorouracil (5-FU) has been used in clinical practice since the 1960s. It is a structural analogue of thymine that blocks DNA synthesis by inhibiting thymidylate synthetase. Topical 5-FU is commercially available as a 0.5 percent cream carried in a microsphere vehicle, as a 1 percent solution or 1 percent cream, as a 2 percent or 5 percent solution, and as a 5 percent cream. The solution can also be used for intralesional injection.

Indications

5-FU 5 percent cream has been approved by the U.S. Food and Drug Administration (FDA) since 1970 for the treatment of actinic keratoses in any location; 5-FU 0.5 percent cream is FDA approved for treatment of actinic keratoses of the face and anterior scalp. 5-FU is used twice daily until an inflammatory response is seen, usually 2 to 4 weeks. The 0.5 percent cream can be used once daily. 5-FU may also be a useful adjunct before cryosurgery of actinic keratoses.[1] Pre-treatment with a keratolytic agent, prolonged therapy, more frequent applications, or the use of occlusive dressings may increase therapeutic response.

Treatment Considerations

Irritation during treatment sometimes requires reduction or interruption of treatment and the addition of emollients or topical corticosteroids to help quell brisk inflammation. A number of approaches to decrease irritation have been devised; whether or not efficacy is preserved is disputed.[2] Weekly pulse dosing involves applying the medication for 1 to 2 days per week for 6 to 7 weeks. Use of the 0.5 percent 5-FU cream with microsphere vehicle may allow for a more tolerable irritation profile.[3]

During 5-FU treatment, previously sub-clinical actinic keratoses, basal cell carcinomas, and squamous cell carcinomas may respond to treatment and become apparent. In fact, the 5 percent 5-FU cream is approved by the FDA for the treatment of superficial basal cell carcinomas. Verrucae vulgaris, verrucae plana, plantar warts, and condylomata acuminata have been treated with varying response rates with topical and intralesional 5-FU. Additionally, actinic cheilitis, mucosal leukoplakia, radiodermatitis, Bowen disease, Bowenoid papulosis, and erythroplasia of Queyrat have all been reported to respond to treatment with topical 5-FU. Further, there are reports of the successful treatment of both psoriasis and keratoacanthomas with topical and intralesional 5-FU,[4] and of infantile digital fibromatosis treated with intralesional 5-FU.[5] Intralesional 5-FU has also been reported to be effective in the treatment of keloids and hypertrophic scars.[6,7]

The systemic absorption of topically applied 5-FU is limited, with absorption selectively greater from abnormal skin than from surrounding normal skin. Microsphere-based formulations may retain 5-FU at the target site, with less drug reaching the systemic circulation.[8] Rarely, systemic effects of 5-FU include nausea and anorexia, stomatitis, diarrhea, myelosuppression, alopecia, and cardiac and neurologic toxicity. Side effects of the topical preparation include local irritation, erythema, pain, swelling, pruritus, dyspigmentation, allergic contact dermatitis, and photosensitivity. Unusual reactions may include onycholysis, onychodystrophy, and the appearance of telangiectasias. The use of injectable preparations may be complicated by pain, local ulceration, erosion, desquamation, and dyspigmentation.[6]

MECHLORETHAMINE (NITROGEN MUSTARD)

Mechanism of Action and Formulations

Mechlorethamine [methyl-*bis* (2-chloroethyl) amine hydrochloride] was the first nitrogen mustard (NM) to be used in clinical medicine. Mechlorethamine acts as an alkylating agent and is not cell-cycle specific; however, its greatest effect is on cells in the late G1 or S phases. The primary target of mustard is the 7-nitrogen atom of guanine. The main role of topical NM in dermatology is in the treatment of the patches and plaques of cutaneous T-cell lymphoma (CTCL). The utility of NM in treating mycosis fungoides (MF), the most common type of CTCL, was first described in 1959. The topical activity of NM has been attributed not only to its alkylating activity, but also to its potential for immune stimulation.[9]

Mechlorethamine hydrochloride (Mustargen) is available in powder form, 10 mg per glass vial. Topical NM is prepared as either an aqueous solution or an ointment preparation. Aqueous solutions can be made to desired concentrations by dissolving the NM powder in tap water (one vial of 10 mg powder dissolved in 100 mL water yields a 10 mg% concentration). The solution is unstable and should be applied immediately to the skin using a sponge or cloth. Ointment preparations can be compounded by pharmacists.[9]

With either preparation, concentrations of 10 to 20 mg% are generally used and are applied daily, with increases in concentration and frequency of application pending clinical response. One approach is to apply the preparation to the entire body (sparingly to intertriginous sites, and excluding the genitalia) initially to avoid missing areas of sub-clinical involvement and thus theoretically increase the potential for cure.[10] Alternatively, treatment may be limited to only clinically affected areas. Treatment should be continued daily until complete response is attained. The benefit of a prolonged maintenance period in preventing disease relapse has not been shown.[9] With proper application, there is minimal contamination of the surrounding environment, but those assisting in the application of the drug should limit their exposure and wear protective gloves. Effort should be made

TOPICAL CYTOTOXIC AGENTS AT A GLANCE

- Topical and intralesional cytotoxic agents are effective in skin cancers and inflammatory and infectious dermatologic conditions.
- They aim for maximum efficacy against cutaneous targets while sparing normal tissue and minimizing systemic toxicity.
- They comprise 5-fluorouracil, nitrogen mustard, carmustine, vinblastine, bleomycin, methotrexate, podophyllin, and miltefosine.

to dispose of empty vials or unused solution in accordance with Environmental Protection Agency guidelines.

Indications

Many large retrospective series support the use of topical NM in MF. NM has been reported to produce complete response rates of 67 percent to 80 percent for MF patients with limited patch/plaque disease (stage IA) and 35 percent to 68 percent for patients with generalized patch/plaque (stage IB) disease.[9] The efficacy of aqueous and ointment-based preparations is similar. Topical NM as primary monotherapy has limited use in patients with tumor stage or erythrodermic disease.[9] Topical NM has also been used in the treatment of psoriasis,[11] alopecia areata,[12] and histiocytosis X.[13]

Treatment Considerations

Unlike the systemic preparation, there are no reports of systemic side effects following topical NM application. Furthermore, topical NM has been used safely in pediatric patients.[9] Local side effects include irritant or allergic contact dermatitis, immediate-type hypersensitivity, secondary cutaneous malignancies, and dyspigmentation. Irritant contact dermatitis is generally mild and resolves with reduction in concentration and/or frequency, or with topical steroid treatment. Allergic contact dermatitis has been reported to develop in up to 35 percent to 66 percent of patients on long-term treatment with aqueous NM and in fewer than 10 percent of those using the ointment preparation.[9] If hypersensitivity occurs, patients may be treated with dilutions below the threshold for clinically observable contact dermatitis. However, delayed-type hypersensitivity may be of therapeutic benefit. Twice-weekly dosing of topical NM in combination with betamethasone cream may offer a balance of tolerability and efficacy.[14] Up to 8 percent of patients may develop an urticarial immediate-type hypersensitivity to topical NM, often necessitating treatment discontinuation. Changes in pigmentation may also occur secondary to use of topical mechlorethamine. Hyperpigmentation and hypopigmentation are prone to develop in areas of previous CTCL and tend to resolve spontaneously, although slowly.

There have been reports of secondary cutaneous malignancies developing in patients treated with NM, including basal and squamous cell carcinomas, keratoacanthomas, and isolated reports of lentigo maligna and primary melanoma.[9] It is difficult to determine causality in these cases, as many of these patients were treated with multiple therapies, including known carcinogenic therapies such as psoralen and ultraviolet A phototherapy and radiation.

BISCHLOROETHYLNITROSOUREA (CARMUSTINE)

Mechanism of Action and Formulations

Carmustine [bischloroethylnitrosourea (BCNU)] is a nitrosourea that acts by alkylation to inhibit DNA, RNA, and protein synthesis. The topical formulation, introduced in 1971, is used primarily in the treatment of CTCL.

BCNU is available as a powder for reconstitution as a solution or ointment at either 10 mg or 20 mg/dL and is applied once daily (BiCNU). The ointment is easier for patients to use and leads to fewer cutaneous reactions. However, it is associated with an increased incidence of myelosuppression. Application should spare the face, hands, genitals, and intertriginous areas, unless these are directly involved with CTCL. The applications should be continued until clearing is seen, usually in 8 to 16 weeks. If the response to 10 mg daily is inadequate, the dose may be doubled for a further 4 to 8 weeks, if tolerated.

Indications

Several large retrospective cases series have shown that BCNU is effective in patch- and plaque-stage CTCL. Complete response rates of 86 percent for those with limited extent (< 10 percent) plaques (T1), 48 percent for those with extensive (≥ 10 percent) plaques (T2), and 21 percent for those with erythroderma have been reported.[15] Median time to complete response has been reported to be 11.5 weeks, with remission durations ranging from 18 to 66 months.[15]

Treatment Considerations

During topical treatment, mild myelosuppression and leukopenia have been reported and therefore patients should be monitored while on treatment.[16] Cutaneous reactions to topical treatment are very common, and a maximum of 6 months of therapy has been recommended. Erythema is seen in almost all patients and may be severe, persistent, and associated with skin tenderness and telangiectasia. Contact dermatitis is less commonly seen with BCNU than with NM, with delayed-type hypersensitivity reactions occurring in fewer than 10 percent of patients. Urticaria is not seen, and an increased incidence of skin cancers has not been observed.

VINBLASTINE

Mechanism of Action and Formulations

Vinblastine, a vinca alkaloid, is an antimitotic agent that acts by disrupting microtubules, thus blocking cell division in metaphase. In dermatologic practice, this agent is used primarily as an intralesional therapy for cutaneous and oral lesions of Kaposi sarcoma.

Concentrations of vinblastine used for intralesional injection in Kaposi sarcoma generally range from 0.1 to 0.6 mg/mL of normal saline. Lower concentrations are used on the eyelids and genitalia. Vinblastine is injected in quantities sufficient to blanch the entire lesion. Some authors use one injection only, whereas others recommend injections every 2 to 4 weeks until complete response is seen. Small controlled prospective studies have shown complete or partial clinical response in 88 percent of treated patients.[17]

Treatment Considerations

Potential systemic side effects of intravenous vinblastine include myelosuppression, neuropathy, anorexia, nausea, vomiting, diarrhea, alopecia, mucositis, and dermatitis. Although side effects from intralesional injection are usually local, there have been reports of mononeuropathy and a transient flu-like syndrome after treatment.[18] Common cutaneous side effects of intralesional injection include pain, especially post-treatment, and post-treatment hyperpigmentation. Intense local reactions and transient or permanent alopecia of treated sites may also result.[18]

BLEOMYCIN

Mechanism of Action and Formulations

Bleomycin is a cytotoxic antibiotic produced by *Streptomyces verticillatus*. Bleomycin disrupts DNA synthesis and causes scission of DNA strands. Bleomycin also has a sclerosant effect on endothelial cells. In dermatology, intralesional bleomycin has largely been used in the treatment of recalcitrant viral warts.

Bleomycin is available as a powder (Blenoxane). It should be reconstituted with sterile saline to the desired concentration, generally 1 U/mL solution. Stability in this formulation has been shown at 6 to 8 weeks if the preparation is refrigerated at 4°C (39.2°F), and for several months if stored at –20°C (–4°F).

Indications

There have been no large, randomized, double-blind, placebo-controlled studies of intralesional bleomycin treatment of viral warts. A paired, controlled study of intralesional bleomycin 1 U/mL injected intralesionally until blanching in resistant warts in 38 patients reported a 77 percent cure rate for warts on extremities; however, the rate fell to about 48 percent for plantar warts.[19] To overcome the problem of adequate infiltration of the wart without unwanted infiltration of normal skin, various approaches, including repeated pricking of the wart,[20] the use of bifurcated needles,[21] and pre-treatment with pulsed dye laser,[22] have been described. An uncontrolled study of 70 patients with plantar, palmar, mosaic, and periungual warts treated monthly with "pricking" of 1 U/mL bleomycin solution using a Monolet needle reported a 92 percent success rate.[20]

Multiple prospective studies of hemangiomas treated with intralesional bleomycin have reported significant reduction in size of lesions in approximately three-fourths of patients.[23,24] Successful treatment of keloids and hypertrophic scars[25] has been reported in several case series, with complete regression in one-half to three-fourths of cases. A small randomized controlled trial and open-label prospective study have described the benefit of topical 1 percent bleomycin in dimethylsulfoxide in treating oral leukoplakia.[26] Isolated case reports and small series have reported benefit from topical bleomycin ointment in treating recurrent Paget disease of the vulva[27] and intralesional bleomycin in treating keratoacanthomas.[28]

Treatment Considerations

Bleomycin has relatively low toxicity. Flu-like symptoms have been reported after intralesional use, but significant systemic toxicity is rare. Pulmonary fibrosis has been well described in association with systemic bleomycin chemotherapy but is dose-related. Local side effects of pain and swelling are common with intralesional use. Combinations of bleomycin and lidocaine may reduce the pain associated with injection, but children may require general anesthesia for treatment. Local injection for periungual warts may result in permanent nail loss or dystrophy.[29] Raynaud phenomenon, dyspigmentation, ulceration, cellulitis, and superficial scarring may also occur.[23,30] There is a case report of flagellate hyperpigmentation after intralesional injection of bleomycin.[31]

METHOTREXATE

Mechanism of Action and Formulations

Methotrexate is an antimetabolite that interferes with DNA synthesis through inhibition of dihydrofolate reductase. Methotrexate also alters the metabolism of adenosine, an endogenous anti-inflammatory mediator.[32]

Indications

In multiple case reports[33] and small case series,[34] intralesional methotrexate has been used to effectively treat solitary, giant, and eruptive keratoacanthomas. Injection parameters have included total doses from 5 to 75 mg, in one to five injections, with single doses ranging from 5 to 50 mg, and intervals of 1 to 2 weeks between injections.

Treatment Considerations

Methotrexate has well-studied adverse effects, including hematologic toxicity, hepatotoxicity, nausea, abdominal pain, oral aphthae, and reversible alopecia. Pancytopenia has been reported to have occurred at a minimum cumulative methotrexate dose of 10 mg and after a single intradermal infiltration of 25 mg.[33] Caution is warranted when using methotrexate in patients with renal insufficiency, advanced age, hepatic disease, or use of medications that may interfere with its excretion.[33] Pregnant or breast-feeding patients must be excluded. Injections have been reported to be generally well tolerated, with moderate pain and minimal scarring.

PODOPHYLLIN AND PODOPHYLLOTOXIN

Mechanism of Action and Formulations

Podophyllin is a crude resin derived from either the American mandrake, *Podophyllum peltatum*, or the Indian podophyllum, *P. emodi*. Podophyllotoxin is an extract of podophyllin with antineoplastic and antiviral activity. Podophyllotoxin binds tubulin, disrupting the cellular cytoskeleton.[35]

Podophyllin is produced as a 10 percent to 40 percent ethanolic or benzoin crude extract. Composition is not standardized, and the most potent active ingredient, podophyllotoxin, rapidly crystallizes out, leading to a short shelf life.

Indications

In dermatology, topical podophyllin and podophyllotoxin are used in the treatment of anogenital warts.

Treatment Considerations

Podophyllin should be applied under medical supervision with a protective inert ointment to surrounding skin and washed off 4 to 6 hours after application. Treatment is generally at weekly intervals.[36] Podophyllotoxin, the purified active ingredient of podophyllin, is available as 0.5 percent ethanol and 0.15 percent cream formulations. These preparations are to be self-applied in one or several 3-day cycles.[36] Self-treatment with podophyllotoxin has been shown to be more effective and more cost-effective compared with podophyllin applied in the clinic, although relapse rates are high with both treatments.[37] Systemic toxicities—including central nervous system and respiratory depression—have been reported after excessive podophyllin treatment of large anogenital warts, subdermal injection, or accidental ingestion, and podophyllin is reported to have mutagenic potential.[36] Local side effects, such as erythema, erosions, and tenderness, are common with both podophyllin and podophyllotoxin. Scarring or depigmentation rarely occurs. Given reports of the low efficacy, high toxicity, and mutagenicity profile of podophyllin, some authors have urged that it be removed from clinical treatment protocols and replaced by podophyllotoxin or other treatments.[36]

MILTEFOSINE (HEXADECYLPHOSPHOCHOLINE)

Mechanism of Action and Formulations

Miltefosine (hexadecylphosphocholine) is a cytotoxic alkyl phosphocholine that exerts its effects on the cell membrane. Miltefosine promotes phospholipid turnover and modulates membrane signal transduction, including inhibition of protein kinase C.

Miltefosine is available as a 6 percent solution in a defined mixture of three short-chain glycerol ethers that increases penetration (Miltex).

Indications

Miltefosine has shown promise as a treatment for cutaneous metastases from breast cancer and cutaneous lymphomas. However, limited skin penetration, local metabolism, and clearance via dermal blood vessels may interfere with efficacy.[38] There are also isolated reports of the successful use of miltefosine in the treatment of cutaneous metastases of squamous cell carcinoma.[39]

Treatment Considerations

Application in clinical trials and case series is generally daily for a week, then twice daily thereafter. Miltefosine 6 percent solution applied in this manner showed modest efficacy against cutaneous metastases of breast cancer in a randomized, double-blind, placebo-controlled, multicenter trial.[40]

When administered systemically, miltefosine causes significant gastrointestinal toxicity. However, systemic side effects, such as nausea, vomiting, and anorexia, have rarely been observed with topical application.[40] Local skin reactions are common, including burning, erythema, and fine scaling, but rarely necessitate discontinuation of therapy.[38]

CHAPTER 221

Topical Immunomodulators

Robert Sidbury
Jon M. Hanifin

The topical immunomodulators are nonsteroidal agents that act via immunologic pathways to either inhibit or enhance immune and inflammatory reactions in the skin. The anti-inflammatory compounds pimecrolimus and tacrolimus are both within the macrolactam class of immunophilin-binding cytokine inhibitors. In the immune-enhancing category, there is currently only one drug, the interferon (IFN)-inducing agent, imiquimod, although several in vitro analogs have proved more potent and are presently under clinical investigation.

MECHANISM OF ACTION AND CLINICAL RESULTS

Topical Calcineurin Inhibitors

The mechanism of action involves tacrolimus binding to the immunophilin-binding protein, in turn blocking calcineurin dephosphorylative activation of the nuclear factor of activated T cells, which translocates to the nucleus where it initiates cytokine gene expression[1] (Fig. 221-1). In vitro effects include inhibition of T-cell proliferation and inhibition of production of a variety of cytokines, including interleukin 2 (IL-2), IL-3, IL-4, IL-12, tumor necrosis factor, and IFN-γ.[2]

Tacrolimus is one to two logs more potent than cyclosporin, its molecular weight is less, and its ability to penetrate the skin is greater. These properties provided a basis for experiments demonstrating topical inhibition of contact hypersensitivity and then development as an ointment for treating atopic dermatitis.

With topical tacrolimus therapy, more than 70 percent of patients have had moderate to excellent improvement in 3-week controlled trials, and 30 percent to 40 percent have had greater than 90 percent improvement.[2] In general, response to therapy with topical tacrolimus has been best and most rapid in thinner skin areas such as the face, neck, and trunk. During remissions, dosing may be reduced in frequency, but flares occur with discontinuance. Response is slow, over days to weeks, and often incomplete on extremities, especially hands and feet, and in patients with lichenified lesions. Roughly 25 percent of patients, especially those with the most severe disease, do not have a satisfactory therapeutic response. Additionally, patients should realize that exacerbations of atopic dermatitis may occur and require occasional intervention with topical or systemic corticosteroid therapy. The main advantage of topical tacrolimus is the provision of chronic maintenance therapy without the need for continuous topical corticosteroids. Koo et al. recently demonstrated up to 91 percent reduction in affected body surface area in a study of nearly 8000 adults and children using topical tacrolimus for up to 18 months without significant adverse events.[3] Other long-term studies with tacrolimus have specifically shown no evidence of cutaneous atrophy, little or no increased infection other than a slightly increased rate of herpes simplex virus in some trials, hypertension, renal toxicity, or cumulative blood levels in patients older than 2 years of age.[4]

Adverse effects have been primarily an intense burning and itching in 30 percent to 40 percent of patients at application sites, especially in areas of flaring, excoriation, and erosion.[2,4,5] These symptoms usually subside in a few days, in concert with healing of the skin. However, some patients continue to have bothersome burning, and this effect seems to be more prominent when the skin is exposed to heat such as during summer weather, or in baths or hot tubs. In general, these problems with burning sensations seem to be less in children. Up to 10 percent of adults experience symptoms of flushing with alcohol ingestion. Infections have

TOPICAL CALCINEURIN INHIBITORS PIMECROLIMUS AND TACROLIMUS AT A GLANCE

- Topical nonsteroidal anti-inflammatory agents.
- U.S. Food and Drug Administration approved for the short-term and intermittent long-term therapy of atopic dermatitis in patients older than 2 years.
- Targeted reduction of pro-inflammatory cytokines putatively responsible for the itch and rash of atopic dermatitis.
- Extensively studied, with an excellent record of short-term safety and efficacy when used appropriately.
- Burning and stinging at the application site is the most common adverse event occurring in 10 percent to 40 percent.
- Theoretical risk of systemic immunosuppression and malignancy have resulted in the addition of a post-marketing black box warning label.
- Widespread off-label use has been discouraged until long-term safety is more definitely established.

not been a notable problem in tacrolimus-treated patients.[2,4] Occasional staphylococcal skin infections occur, but they are no worse than before treatment, and studies actually demonstrate a reduction in *Staphylococcus aureus* colonization during prolonged therapy. In spite of the theoretical concern about immunosuppression, there have been no significant increases in frequency or severity of warts, varicella, or molluscum contagiosum infections. Some cases of eczema herpeticum have been noted in clinical trials. All continue to occur as usual in these patients with atopic dermatitis, but severity is unremarkable. Immunosuppression also carries the theoretical risk of cutaneous cancer and lymphoma predisposition but, to date, there has been no evidence of increased risk of occurrence relative to the general population. A smattering of post-marketing reports of lymphoma or malignancy in patients using tacrolimus topically, coupled with a biologically plausible risk related to topical calcineurin inhibitor (TCI) use, were factors in the U.S. Food and Drug Administration (FDA) calling for a black box warning label. Extensive review of these reports by independent oncologists and allied task forces has not found evidence of an increased risk of lymphoma or malignancy.[6–8] However, such effects require many years of constant immunosuppression, and thus, close surveillance is indicated along with careful counseling of patients to use sun protection.

Pimecrolimus has a very similar structure to tacrolimus and interacts with the same binding protein to inhibit calcineurin activation of the nuclear factor of activated T cells.[9] Cutaneous effects are lower, however, as reflected by decreased protein-binding affinity, which necessitates a higher drug concentration in the topical cream.[4] Topical pimecrolimus also appears to have little systemic immunosuppressive effect, which may reflect a wider margin of safety. Clinical trials have included infants as young as 3 months of age, although FDA approval has been limited to 2 years of age and older. A recent study of 76 infants and children revealed sustained benefit without significant adverse effect with pimecrolimus therapy for 2 years.[10] Two patients in the study developed eczema herpeticum. As with tacrolimus, occasional post-marketing reports of lymphoma and malignancy moved the FDA to affix the black box warning label to the entire class of medication, but these concerns remain at present theoretical.[6] Blood levels have been detected in occasional patients, but no high or prolonged levels have been detected. Initial studies of oral pimecrolimus were promising, but, in the wake of the black box controversy, development has been suspended.

Imiquimod

Imiquimod is unique in that it appears to enhance both acquired and innate immune function.[11] In comparison, TCIs inhibit pathways involved in immune activation. In vitro and in vivo studies demonstrate that topically applied imiquimod induces local cytokine production from keratinocytes and other cells.[12] Imiquimod's activity is mediated through the Toll-like receptor (TLR7 and TLR8) signaling cascade, resulting in the secretion of pro-inflammatory cytokines. In vitro effects include induction of IFN-α and IFN-γ, tumor necrosis factor-α, IL-1, IL-1 receptor antagonist, IL-6,

IMIQUIMOD AT A GLANCE

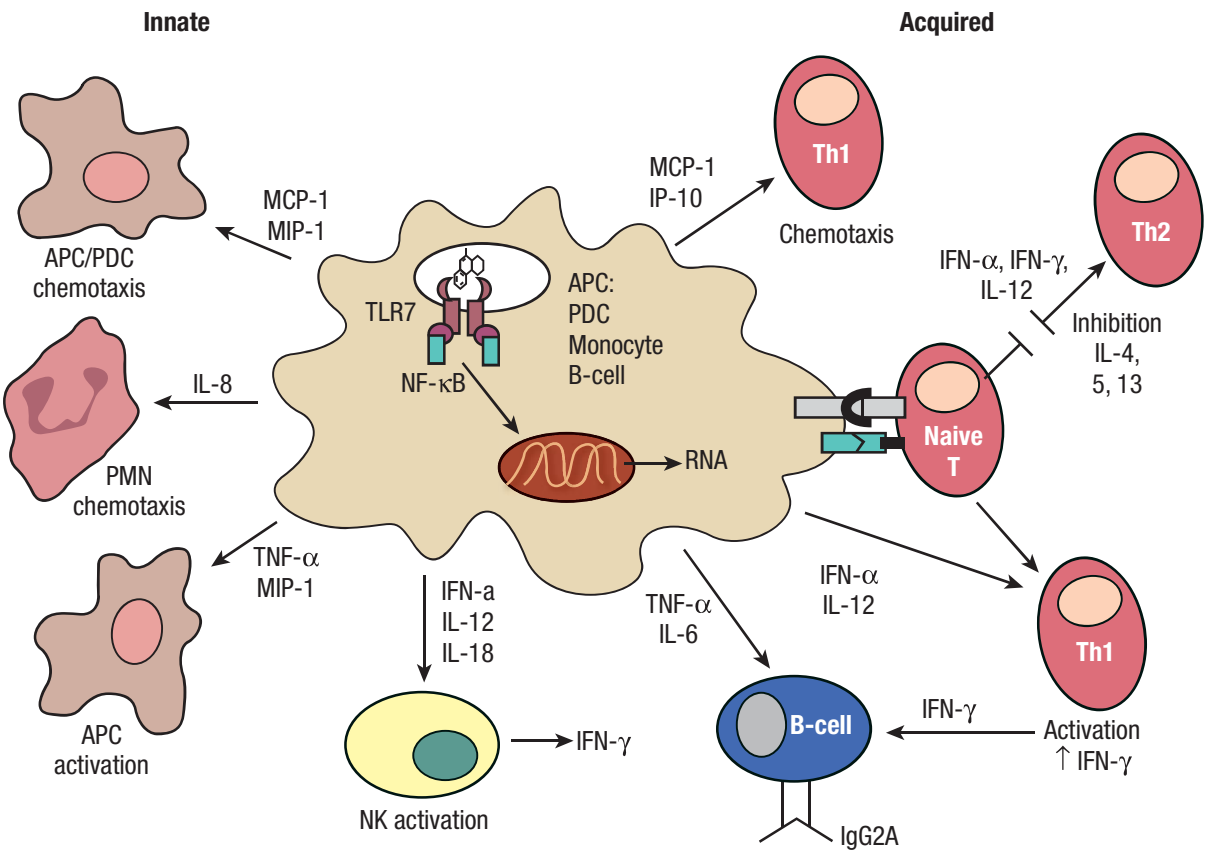
- Topical immunotherapy indicated for anogenital warts, superficial basal cell carcinoma, and actinic keratosis.
- Small molecule immune response modifier in the imidazoquinoline family.
- Induces heterogeneous, immune-mediated responses including antiviral, antitumoral, anti-angiogenic, and vaccine adjuvant activity.
- Targeted therapy that results in production of the inflammatory cytokines tumor necrosis factor-α and interferon-γ, thereby enhancing cell-mediated immune response.
- Application site stinging and irritant contact dermatitis are the most common adverse events.

IL-10, IL-12, granulocyte colony-stimulating factor, granulocyte-monocyte colony-stimulating factor, as well as the chemokines IL-8, macrophage inflammatory protein 1α, and monocyte chemotactic protein 1[13,14] (Fig. 221-2). Imiquimod also stimulates the innate immune response by increasing natural killer cell activity, activating macrophages and Langerhans cells, and inducing proliferation and maturation of B lymphocytes. Additionally, imiquimod has direct proapoptotic activity on tumor cells.

Many published reports show that imiquimod is an effective treatment for anogenital warts. A 16-week study of 311 immunocompetent adults with external anogenital warts compared three times weekly 5 percent imiquimod cream, 1 percent imiquimod cream, and placebo.[15] Clearance was achieved in more than 70 percent of women and 30 percent of men with the 5 percent cream, both significantly better than placebo. Response rates greater than 30 percent have been seen in uncircumcised males treated under the foreskin, suggesting that increased moisture may account for this gender discrepancy. Similarly, local factors may account for lower response rates in non-genital warts. The primary benefit of imiquimod cream relative to other available wart therapies is ease of administration. In adults, home therapy for genital warts is preferred, given the sensitive nature of this problem. Likewise in children, genital warts may be a result of sexual abuse, and an atraumatic topical therapy that can be rapidly applied in a nonthreatening environment is ideal. Recurrence rates following use of imiquimod cream have ranged from 13 percent to 19 percent.[15]

Adverse effects relate primarily to cutaneous irritation at the application site, leading to moderate erythema and erosion in roughly one-third and one-tenth of patients, respectively. Studies suggest that both the response rate, particularly in males, and the likelihood of side effects will increase with daily therapy. Imiquimod is a category C drug, and it is not known to what extent topically applied imiquimod is excreted in the breast milk of nursing mothers. Imiquimod has not been thoroughly studied in children younger than 18 years of age. Imiquimod has been investigated for a variety of other infectious conditions with varying degrees of success.

In vitro evidence of antitumor effects formed the basis for evaluation of imiquimod's efficacy in the treatment of cutane-



▲ **FIGURE 221-2** Mechanism of action by imiquimod. ous neoplasia. A multicenter, randomized, open-label dose-response trial showed an almost 90 percent histologic clearance rate of superficial basal cell carcinoma (BCC) when 5 percent imiquimod cream was applied daily for 6 weeks. Twice daily application led to an improved response rate but a higher incidence of local skin reactions.[16] Geisse et al. subsequently reported that two phase III double-blind, randomized, vehicle-controlled trials showed histologic clearance of 82 percent with five times weekly treatment. Daily therapy was no more effective, and response was positively correlated with signs of inflammation, including erythema, erosion, and crusting.[17] These studies formed the foundation for approval of truncal/extremity superficial BCC as an indication for imiquimod therapy.[12]

Imiquimod has also been approved as a treatment for actinic keratosis of the head and neck. Hadley et al. recently reviewed the use of imiquimod for actinic keratosis. In five randomized controlled trials lasting 12 to 16 weeks involving 1293 patients, complete clinical clearance was seen in 50 percent of imiquimod patients versus 5 percent using vehicle. Adverse events were significantly higher in imiquimod-treated groups, including erythema (27 percent), crusting/scabbing (21 percent), flaking (9 percent), erosion (6 percent), edema (4 percent), and weeping (3 percent).[18]

Although not yet clinically indicated as an anti-angiogenic agent, imiquimod has demonstrated anti-angiogenic properties in vitro and in a series of case reports. Imiquimod's anti-angiogenic properties stem from the production of anti-angiogenic cytokines, including IFN-γ, IL-10, and IL-12; the upregulation of endogenous anti-angiogenic mediators, including tissue inhibitor of matrix metalloproteinase; and downregulation of the pro-angiogenic factors basic fibroblast growth factor and matrix metalloproteinase 9.[19] In a mouse model of hemangioendothelioma, imiquimod application resulted in fewer and smaller tumors, and numerous clinical reports have noted clinical response treating vascular neoplasms, including hemangiomas of infancy and pyogenic granulomas.[20] Future trials must better define imiquimod's role in the treatment of various vascular lesions.

PHARMACOKINETICS

Pimecrolimus and Tacrolimus

Tacrolimus ointment, 0.03 percent and 0.1 percent applied twice daily, was studied extensively in clinical trials that included adults and children as young as 2 years of age.[1] Pharmacokinetic studies showed percutaneous absorption initially in 10 percent to 20 percent of patients with atopic dermatitis, but generally blood levels were undetectable by 1 week as healing and re-establishment of the skin barrier occurred. Rarely were blood levels greater than 2 ng/mL (compared with trough levels of 5 to 15 ng/mL in transplant patients treated systemically).[2]

In an open label study of twice-daily pimecrolimus use in infants ranging in age from 5.7 to 11.9 months at baseline with moderate to severe atopic dermatitis, Lakhanpaul et al. found no accumulation of drug and systemic levels ranging from below the limit of detection to 1.94 ng/ml. There were no significant adverse events over the course of this 1-year-long trial.[21]

Imiquimod

The half-life of systemically administered imiquimod, either oral or subcutaneous, is 2 to 4 hours in healthy volunteers. The half-life of intravenously administered imiquimod is 14 hours, and less than 1 percent of the drug is recovered in the urine after a single topical application. The major systemic metabolite of imiquimod, S26704, is a hydroxylation product that achieves plasma concentrations of less than 20 percent of the parent compound.[22] Higher levels have been noted with both intravaginal administration in healthy volunteers or systemic administration in chronically ill patients. With topical administration in healthy volunteers, there is very little measurable imiquimod (pg/mL) and no detectable S26704.

INDICATIONS: U.S. FOOD AND DRUG ADMINISTRATION AMENDED INDICATIONS

Pimecrolimus and Tacrolimus

- Second-line therapy for atopic dermatitis
- Children older than 2 years
- Adults
- Short term, non-continuous chronic therapy

Imiquimod

- External anogenital warts
- Superficial BCC smaller than 2 cm on trunk, neck, extremities
  - Immunocompetent adults
  - When surgical options less appropriate
  - Biopsy-confirmed
- Actinic keratosis

CONTRAINDICATIONS

Pimecrolimus and Tacrolimus

- Immunocompromised
- Netherton syndrome
- Active bacterial or viral infection
- Phototherapy

Imiquimod

- Immunocompromised
- Refractory, thicker, actinic keratoses

DOSING REGIMENS

INITIATING THERAPY

Pimecrolimus and Tacrolimus

In light of recent concerns with long-term safety and questions raised by the widely publicized black box warning label, initiation of TCI therapy should begin by addressing parent and patient concerns. These agents should be considered second line and are indicated when standard therapy, including topical steroids and emollients, are either ineffective or harmful. Comparisons of these agents with standard therapy have not as yet consistently shown a relative clinical or pharmacoeconomic benefit compared with topical steroids.[23] Once the decision to initiate TCI therapy has been made, consideration must be given to the choice of either pimecrolimus or tacrolimus. Pimecrolimus is available as a 1 percent cream formulation and is indicated for mild to moderate atopic dermatitis. Tacrolimus is available in two strengths, 0.03 percent for children ages 2 to 15 years old, and 0.1 percent in patients 16 years and older. Topical tacrolimus has an ointment vehicle and is indicated for moderate to severe atopic dermatitis.

Both products have been extensively studied and have excellent safety and efficacy records compared with placebo in the short term. Therefore, patient vehicle preferences and disease severity help determine the appropriateness of either agent for an individual patient. Paller et al. found tacrolimus to be more effective than pimecrolimus with a similar side effect profile in three comparison trials.[24]

Pimecrolimus or tacrolimus should be applied sparingly only to affected areas of skin twice daily. The smallest amount of

medicine should be used, and therapy discontinued where signs and symptoms of redness and itch have resolved for 1 week. Adjunctive therapies such as emollients should be continued. If applied after bathing, as often recommended, pimecrolimus or tacrolimus should be applied first to affected areas, and emollients subsequently to unaffected skin. Application site stinging from TCIs may be more severe in areas of excoriation. Efforts to limit these open areas of skin by pre-treating for 2 to 7 days with a topical steroid may improve adherence to therapy.

Imiquimod

Imiquimod should be applied sparingly to affected areas when treating warts or superficial BCC. A broader but circumscribed treatment area is recommended either on the face or scalp, but not both, when treating actinic keratosis. For anogenital warts, initial frequency should be three times weekly. If little or no effect is seen after 2 to 4 weeks, advancing to daily use may enhance efficacy, although risk of an irritant dermatitis will increase commensurately. Application before sleeping is generally recommended and imiquimod should be left on the skin for 6 to 10 hours. It should be made clear to patients treating warts that imiquimod therapy does not eliminate the risk of transmission of papilloma virus to physical contacts. The frequency of application for the treatment of superficial BCC (five times weekly) and actinic keratosis (two times weekly) differs as noted in the boxes.

MONITORING THERAPY

Pimecrolimus and Tacrolimus

If effective, TCIs may be incorporated into the long-term therapeutic regimen for atopic dermatitis. Prescribing physicians must assure that patients are using these products intermittently and only to treat active dermatitis. Adverse events, including application site reactions, should be monitored. Patients should be evaluated for cutaneous infections with particular vigilance against eczema herpeticum, which was noted with slightly increased frequency in some pre-marketing trials. Any evidence of lymphadenopathy should be documented and followed closely. Skin examinations for signs of cutaneous malignancy are prudent. No routine serologic monitoring is indicated; however, if clinical evidence suggests the possibility of systemic immunosuppression, serum levels of tacrolimus or pimecrolimus may be obtained. If blood levels are sought, care must be taken to first remove any residual medication, particularly at the antecubital location, a common site for both venipuncture and atopic dermatitis. Failure to do so may lead to spuriously elevated drug levels. Despite reassuring safety data, the lesson of the black box controversy is that definitive long-term safety has not been established; and therefore, ongoing vigilance for potential TCI adverse effects, including immunosuppression and malignancy, must continue.

Imiquimod

Imiquimod therapy for warts, if tolerated, should be continued until complete clearance of warts or a maximum of 4 months before declaring a treatment failure. If no response or clinical deterioration is seen at 8 weeks, other therapeutic options should be entertained. If an incomplete response is obtained, continuing therapy may be warranted. Increasing from three times weekly to daily treatment may be indicated if imiquimod is well tolerated. No serologic monitoring is necessary. Irritant reactions may be treated initially by temporary cessation of therapy in addition to or followed by appropriate topical anti-inflammatory intervention. Imiquimod therapy can then be resumed as necessary at a decreased frequency as indicated. Similar principles govern the use of imiquimod for superficial BCC and actinic keratosis, but closer clinical follow-up is indicated.

RISKS AND PRECAUTIONS

Pimecrolimus and Tacrolimus

- Application site reactions, including itch, burning, stinging, redness, flushing with alcohol
- Avoid use on pre-malignant or malignant skin conditions, including cutaneous T-cell lymphoma
- Skin infections, including *S. aureus*, dermatophytosis, and herpes simplex
- Lymphadenopathy
- Light exposure, including phototherapy
- Immunocompromised
- Netherton syndrome
- Renal insufficiency
- Pregnancy category C
- Lactation
- Flu-like symptoms
- Worsening acne

Imiquimod

- Erythema, erosion, edema, ulceration, excoriation/flaking
- Hypo- or hyperpigmentation
- Pregnancy category C
- Safety not established in children younger than 12 years old
- Soreness
- Flu-like symptoms
- Myalgia
- Headache
- Multiple treatment courses for superficial BCC or actinic keratosis at same site
- Basal cell nevus syndrome
- Superficial BCC of the head, neck, or anogenital area
- Xeroderma pigmentosum

COMPLICATIONS

Pimecrolimus and Tacrolimus

- Elevated blood levels and risk of systemic immunosuppression
- Unclear long-term risk of lymphoproliferative disease
- Unclear long-term malignancy risk
- Eczema herpeticum

Imiquimod

- Irritant contact dermatitis
- Ulceration
- Incomplete treatment of malignancy

CHAPTER 222

Other Topical Medications

Craig N. Burkhart
Kenneth A. Katz

This chapter reviews topical therapies not covered elsewhere in the text that are used to treat dermatologic diseases. The topic headings are those of the drug designation of the U.S. Pharmacopeia and at times reflect clinical usage rather than specific pharmacologic mechanisms.

ANALGESICS

Capsaicin

Capsaicin is the molecule that confers the "hotness" to hot peppers of the genus *Capsicum*, including cayenne, jalapeno, and Tabasco peppers.[1] Initial topical application results in itching, pricking, and burning as nociceptor activate. Repeated applications, however, are hypothesized to lead to degeneration of epidermal nerve fibers and nociceptor desensitization, thereby producing hypalgesia.[2]

Topical capsaicin has been used to treat postherpetic neuralgia, diabetic neuropathy, reflex sympathetic dystrophy, Raynaud phenomenon, nostalgia paresthetica, arthralgias, plantar warts, diabetic neuralgia, and hemodialysis-related pruritus.[3] A recent systematic review of treatments for postherpetic neuralgia concluded that early use of capsaicin should be considered as a first-line agent for postherpetic neuralgia in some cases.[4]

Topical Anesthetics

Eutectic mixture of local anesthetics (EMLA) cream contains the sodium-channel–blocking amide anesthetics lidocaine 2.5 percent and prilocaine 2.5 percent. Application under occlusion to intact skin or genital mucous membranes for at least 1 hour before performance of a painful procedure provides local anesthesia that may persist for up to 2 hours. The cream may cause transient local blanching followed by transient local erythema. Like all products containing lidocaine, it should not be used in patients with hypersensitivity to amide anesthetics. Additionally, the prilocaine component has been linked to cases of methemoglobinemia in patients for whom applications exceeded the recommended dose, application area, or application time.[5,6] Those particularly susceptible to methemoglobinemia include patients who are very young, those with glucose-6-phosphate dehydrogenase deficiency, and those taking oxidizing drugs such as sulfonamides and antimalarials.[5]

Caution regarding dosing should also be used in patients susceptible to systemic effects of lidocaine or prilocaine, including acutely ill, debilitated, and elderly patients. Finally, as EMLA is ototoxic, it should not be used if there is a concern that it could penetrate or migrate beyond the tympanic membrane to the middle ear.

Various topical anesthetic products contain only lidocaine, typically at concentrations of 4 percent or 5 percent, which may be applied with or without occlusion. Systemic toxicity from topical lidocaine prepared in a 30 percent concentration has been reported,[7] though lower concentrations are likely much safer.[8] A single case of contact urticaria to EMLA cream has also been reported.[9]

ANTI-INFLAMMATORY AGENTS

Coal Tar

Coal tar has been used to treat inflammatory dermatoses for up to two millennia, although currently it is used primarily to treat psoriasis.[11] Coal tar has been shown to inhibit DNA synthesis and mitosis in epidermal cells, an effect potentiated by ultraviolet A exposure.[12,13] Coal tar also has anti-infective, antipruritic, photosensitizing, and vasoconstrictive effects and, with repeated applications, causes epidermal atrophy.[11] The precise mechanism by which it treats inflammatory skin diseases has not been fully described.[11]

In 1925, Goekerman pioneered the concomitant use of coal tar and ultraviolet B therapy for psoriasis.

Coal tar is messy to use, has an unpleasant odor, and can stain clothing, making its use challenging for some. Systemic adverse effects are uncommon, whereas local adverse effects include allergic or irritant contact dermatitis, erythema, stinging, exacerbation of exfoliative dermatitis or pustular psoriasis, folliculitis, atrophy, telangiectasis, pigmentation, cutaneous horns, keratoacanthomas, and tar warts.[11] Although occupational exposure to coal tar has been associated with increased risk of developing skin cancer, epidemiologic studies of coal tar–treated psoriasis have not demonstrated an increased risk of skin cancer due to coal tar.[11]

Wood Tar

Produced by distillation of wood under controlled conditions, wood tar can be added to arachis oil (peanut oil) or other bases. The preparation is then typically used to treat scalp psoriasis. Most commonly derived from juniper (oil of cade), wood tar may also be derived from beech, birch, and pine.

Shale Oil

Shale oil (also referred to as *ammonium bituminosulphonate*, *ichthyol*, *ichthammol*, or *black salve*) is derived from oil shale, a sulfur-rich sedimentary rock. Further processing of extracted shale oil yields light- and dark-colored components. The light component is also referred to as *pale sulfonated shale oil* (PSSO) or *ichthyol pale*.[16] Shale oil decreases inflammation by inhibiting lipoxygenase.[18] PSSO has been used to treat acne, atopic eczema, psoriasis, seborrhea, eczema, rosacea, and pruritus.[16,19] PSSO may have beneficial effects on wound healing, including venous leg ulcers.[20] Shale oil has also been used to treat otitis externa.[21]

ANTIMICROBIAL AGENTS (Table 222-1)

Chlorhexidine

Chlorhexidine gluconate is a bisbiguanide that binds to the stratum corneum, providing sustained bactericidal and fungicidal activity for over 6 hours, even

OTHER TOPICAL MEDICATIONS AT A GLANCE

- Topical medications not sufficiently covered in other sections of this text comprise
  - Analgetics
  - Anti-inflammatory agents
  - Antimicrobial and antiparasitic agents
  - Antiparasitic agents
  - Antiperspirants, antipruritics and astringents
  - Bleaching and keratolytic agents
  - Topical psoriasis and wart therapies

TABLE 222-1
Topical Antimicrobials and Astringents

Drug	Group	Antibacterial Mechanism	Antimicrobial Spectrum	Major Side Effects or Contraindications	Use (Selected)	U.S. Food and Drug Administration Pregnancy Category
Chlorhexidine	Bisbiguanide	(1) Binds to negatively charged bacterial cell wall and cytoplasmic components leading to altered osmotic equilibrium and (2) precipitation of cytoplasmic components	Gram-positive, Gram-negative bacteria, enveloped viruses, and fungi	Keratitis, ototoxicity	Antiseptic surgical hand scrub and surgical site preparation	B
Gentian violet	Dye	Unknown	Some vegetative Gram-positive bacteria (e.g., *Staphylococcus* sp.) and yeast	Potential skin necrosis at high concentrations or when occluded; stains skin and clothing; tattooing when applied over granulation tissue; mutagenic	Impetiginized eczema; mycotic skin infections; oral candidiasis; superficial skin infections	C
Brilliant green	Dye	Unknown	Similar to gentian violet	Potential skin necrosis; stains skin and clothing	Similar to gentian violet	Not used in Western medicine
Hydrogen peroxide	Peroxide	Oxidizes microbial molecules	Broad spectrum antimicrobial	Avoid in abscesses; bleaches hair	Cleansing of wounds, suppurating ulcers, and local infections	—
Povidone-iodine	Iodophor	Oxidation and release of free iodine	Gram-positive, Gram-negative, enveloped viruses, fungi, sporicidal, *Mycobacterium tuberculosis*	Caution in patients with thyroid disorders; potential systemic toxicity in neonates or when applied to large body surface area; neutralized by blood, serum proteins, and sputum	Antiseptic surgical hand scrub, prevention or treatment of topical site infection associated with surgery, burns, minor cuts/scrapes	C
Clioquinol	Iodophor	Oxidation and release of free iodine; chelates bacterial surface and trace metals needed for bacterial growth	Gram-positive, Gram-negative, enveloped viruses, fungi, sporicidal, *M. tuberculosis*	Possible irreversible optic atrophy and peripheral neuropathy (oral); contraindicated in children < 2 yr of age; contraindicated for diaper rash; stains skin yellow; neutralized by blood, serum proteins, and sputum	Approved for fungal infections; also used for pyoderma, folliculitis, and impetigo	—
Metronidazole	Imidazole	Creation of reduced intermediate compounds and free radicals	Anaerobes, protozoa, and microaerophilic bacteria	Contraindicated during first trimester of pregnancy	Rosacea	B
Mupirocin	Fermentation product of *Pseudomonas fluorescens*	Inhibits bacterial isoleucyl-t-RNA synthetase	Gram-positive, some Gram-negative, spares normal flora	Potentially toxic amounts of polyethylene glycol contained in vehicle may be absorbed in patients with extensive burns or open wounds	Non-bullous impetigo, eradication of nasal carriage of *S. aureus*	B

(continued)

TABLE 222-1
Topical Antimicrobials and Astringents (Continued)

Drug	Group	Antibacterial Mechanism	Antimicrobial Spectrum	Major Side Effects or Contraindications	Use (Selected)	U.S. Food and Drug Administration Pregnancy Category
Azelaic acid	Dicarboxylic acid	Possibly through inhibition of microbial respiratory chain	*Propionibacterium acnes* and *S. epidermidis*	Hypopigmentation	Acne	B
Benzoyl peroxide	Peroxide	Oxidizes microbial molecules	Broad-spectrum antimicrobial	Bleaches dark clothing	Acne	C
Aluminum salts	Astringent	Coagulation of proteins	Broad-spectrum antimicrobial	Do not use under impervious material to prevent evaporation	Weeping, impetiginized skin disorders	—
Potassium permanganate	Astringent	Oxidizes microbial molecules	Broad-spectrum antimicrobial	Skin discoloration; caustic at high concentrations or with contact of undissolved crystals	Weeping, impetiginized skin disorders	—
Silver nitrate	Astringent	Precipitation of bacterial proteins by free silver ions	Gram-positive and Gram-negative bacteria	Black skin discoloration, caustic at high concentrations; potential methemoglobinemia	Weeping, impetiginized skin disorders, cauterization of wounds, removal of granulation tissue, aseptic prophylaxis of burns	C

when wiped from the field. Although it does not kill bacterial spores or mycobacteria, it does inhibit their growth. Because it does not lose its effectiveness in the presence of organic material, such as whole blood, it is an important antiseptic, disinfectant, antibacterial dental rinse, and preservative. Due to ototoxicity and the risk of conjunctivitis and corneal ulceration, chlorhexidine is not recommended for pre-operative preparation of the face or head.

Dyes

Dyes are useful topical treatments because they are inexpensive and chemically and physically stable. The topical antiseptic dyes used in dermatology, gentian violet (methylrosaniline chloride), brilliant green (*p*-diethylamine triphenylmethanol), malachite green, and fuchsine, are all derivatives of triphenylmethane. The dyes are effective against *Candida* species and several aerobic Gram-positive bacteria, including methicillin-resistant *Staphylococcus aureus*. Gentian violet is a known contact sensitizer and may cause skin necrosis in concentrations greater than 2 percent aqueous solution or when used undiluted in skin folds.[22]

Hydrogen Peroxide

Hydrogen peroxide has been used for a number of years as a cleansing agent and for the removal of debris. It has antibacterial properties against both Gram-positive and -negative bacteria, and its effervescent quality helps débride wounds.

Iodinated Compounds

Iodine solution is bactericidal, sporicidal, and viricidal. Iodophors are complexes of iodine with a carrier that slowly liberates inorganic iodine on contact with reducing substances. This preserves the antimicrobial activities of iodine without the irritant effects of the free tincture. Iodophors must be applied to dry skin as they are inactivated by contact with blood, serum proteins, and sputum.

POVIDONE-IODINE Povidone-iodine has a wide spectrum of in vitro activity against Gram-negative and -positive bacteria, fungi, and viruses. Systemic absorption can occur with resultant renal and thyroid dysfunction if large or prolonged quantities are used.

CLIOQUINOL Clioquinol, 5-chloro-8-hydroxy-7-iodoquinolinol, is weakly antifungal and antibacterial. It is effective alone or combined with a topical steroid to treat inflammatory dermatoses, especially in intertriginous areas. Adverse reactions include a yellowish discoloration on clothing or skin, delayed contact hypersensitivity, and contact dermatitis. In the early 1970s, it was linked to subacute myelo-optic neuropathy in Japan[23] and was banned in many countries, including the United States. This link was questioned by subsequent epidemiologic studies,[24] but product labeling still warns of possible irreversible optic atrophy and peripheral neuromuscular disease.

Metronidazole

Metronidazole is an imidazole with activity against anaerobic bacteria and protozoa that is most often used in dermatology for rosacea. In addition to its antibiotic properties, its mode of action in rosacea may involve the impedance of leukocyte chemotaxis and selective suppression of cellular immunity.

Mupirocin

Mupirocin, also known as *pseudomonic acid*, is bactericidal at the concentration achieved with topical application to the skin and mucous membranes. As mupirocin has a unique mechanism of action, in which it prevents the incorporation of isoleucine into proteins by inhibiting bacterial isoleucyl-t-RNA synthetase, there is no cross-resistance with other antimicrobials.[25] It has activity against staphylococci, streptococci, and certain Gram-negative bacteria, but is inactive against much of the normal

skin flora. It is the treatment of choice for nonbullous impetigo and the most effective topical antibiotic for the elimination of *S. aureus* nasal colonization.[25]

Azelaic Acid

Azelaic acid is a naturally occurring aliphatic dicarboxylic acid that is a competitive inhibitor of tyrosinase. Azelaic acid is a reversible inhibitor of cytochrome P_{450} reductase and 5α-reductase in microsomes and a reversible inhibitor of some enzymes in the respiratory chain.[26] In vitro azelaic acid has antimicrobial affects against *Propionibacterium acnes* and *S. epidermidis*.[27] Its efficacy against acne and rosacea is attributed to activity against *P. acnes*, normalization of keratinization, and a direct anti-inflammatory effect.[28]

Benzoyl Peroxide

Benzoyl peroxide is a non-specific bactericidal agent that derives its biologic function through decomposition into benzoyloxy and phenyl radicals that react with numerous constituents of microbial cells. This effect may be enhanced by the addition of antibiotics or other molecules containing tertiary amines or transitional metals.[29] As a topical therapy, benzoyl peroxide is mainly used for acne, although it is also occasionally used to speed healing of chronic wounds.[30] When used for acne, it is frequently combined with topical antibiotics, as such combination therapy may reduce the development of antibiotic resistant by *P. acnes*.[31]

ANTIPARASITIC AGENTS (See Chaps. 207 and 208; Table 222-2)

Crotamiton

Crotamiton (crotonyl-*N*-ethyl-*O*-toluidine) is a colorless or pale yellow oil used in the treatment of scabies, pediculosis capitis, and pruritus. Its mode of action is unknown. Other antiparasitic formulations, such as lindane 1 percent and permethrin cream 5 percent, are more effective than crotamiton,[32] which is rarely a sensitizer. It is approved for use in infants and children, but is pregnancy category C.

γ Benzene Hexachloride

γ Benzene hexachloride, also known as *hexachlorocyclohexane* or *lindane*, is a chlorinated hydrocarbon pesticide that is effective against lice, scabies, and fleas as a 1 percent lotion or shampoo. Scabies and lice resistant to γ benzene hexachloride have been reported.[22] Furthermore, multiple side effects of topical application including central nervous system toxicity, seizures, and aplastic anemia have been reported leading to the U.S. Food and Drug Administration recommendation that γ benzene hexachloride only be used as a second-line agent.[33] Patients with seizure disorders, children weighing less than 50 kg, and patients with acutely inflamed or raw skin should avoid γ benzene hexachloride.

Malathion

Malathion is an organophosphate insecticide that acts by irreversibly binding to acetylcholinesterase.[34] It is approved in the United States as a 0.5 percent lotion for the treatment of head lice. The lotion, containing 78 percent isopropyl alcohol, is flammable. Safety for children younger than 6 years of age has not been established, and it is pregnancy category B.

Permethrin

Permethrin is a synthetic pyrethroid modeled after the natural insecticide found in the pyrethrum flower, *Chrysanthemum cinerariaefolium*. It acts on parasitic nerve cell membranes, causing paralysis and death. It is available over-the-counter as a 1 percent cream rinse, which is left on dry hair for 10 minutes. A single application is often effective against head lice and nits. Due to increasing resistance, however, two applications, 7 to 10 days apart, are generally recommended. There is a lack of safety data for its use in children younger than 2 months of age, and in pregnant and breast-feeding women. Prescription strength permethrin 5 percent cream is also effective against pediculosis capitis resistant to the 1 percent cream, pediculosis pubis, scabies, and mite infestations including cheyletiella.[35] The 5 percent cream is applied to dry skin and hair overnight (8 to 14 hours).

TABLE 222-2
Topical Antiparasitic Agents

Treatment	Group or Composition	Mechanism	Major Side Effects or Contraindications	Use	U.S. Food and Drug Administration Pregnancy Category
Permethrin (1% or 5%)	Synthetic pyrethroid	Inhibits nerve cell sodium ion influx	Itching and stinging on application; contraindicated for infants < 2 mo of age	Lice and scabies; used on clothing as an insect repellant	B
Synergized pyrethrins	Natural botanical	Pyrethrins inhibit nerve cell sodium ion influx; piperonyl butoxide inhibits cytochrome P_{450}	Itching and stinging on application; ragweed or chrysanthemum allergy	Lice	C
Malathion (0.5%)	Organophosphate	Cholinesterase inhibitor	Flammable; not approved for children < 6 yr of age	Lice	B
Crotamiton (10%)	Crotonyl-*N*-ethyl-*O*-toluidine	Unknown	Poor efficacy	Scabies	C
Lindane (1%)	Organochlorine	Cholinesterase inhibitor	May cause seizures, muscle spasms, aplastic anemia; not for use in children < 3 yr, pregnant or breast-feeding women, patients with underlying neurologic disorders, or over broken skin	Lice and scabies	C

TABLE 222-3
Topical Antipruritics

Drug	Group	Mechanism	Precautions	U.S. Food and Drug Administration Pregnancy Category
Diphenhydramine	Antihistamine	Local anesthesia; histamine antagonism	Significant percutaneous absorption; potential sensitization with cross-sensitization to oral diphenhydramine and related compounds	B
Doxepin	Tricyclic antidepressant	Histamine antagonism, interference with neuronal synaptic communication; decreased awareness through production of drowsiness	Potential contact sensitization; significant systemic absorption resulting in drowsiness and drug interactions; contraindicated in patients taking monoamine oxidase inhibitors	B
Menthol	Cyclic terpene alcohol	Counter-irritant. The cooling sensation may be the result of a direct interaction of menthol with cold receptors and/or nerve fibers.[39,44]	—	C when combined with camphor (i.e., Sarna)
Phenol	—	Local anesthesia	Avoid in pregnant women and infants[45]; irritant in diaper area and skin folds	Should be avoided[45]
Pramoxine hydrochloride	Surface anesthetic	Local anesthesia	—	C

Pyrethrins

Pyrethrins are the naturally occurring esters of chrysanthemumic acid. In combination with piperonyl butoxide, it is available as a liquid, gel, oil, aerosol spray, foam, and shampoo. Pyrethrins are neurotoxins, and piperonyl butoxide inhibits pyrethrin metabolism, potentiating the effects of pyrethrins. It is also effective against fleas, mosquitoes, and houseflies. As it is derived from the extract of chrysanthemums, the American Academy of Pediatrics suggests that individuals who are sensitive to chrysanthemums or ragweed should avoid this medication.[36] However, this recommendation is controversial as patch and prick testing of commercially available synergized pyrethrins fail to elicit a response in ragweed-allergic patients.[37] The aerosol spray should never be prescribed to patients with a history of asthma.

ANTIPERSPIRANTS

Aluminum Compounds

Aluminum chloride solutions are typically used for hyperhidrosis in 15 percent to 20 percent solutions in the axilla and up to 30 percent on the palms and soles.[38] The solution is applied for a week at night, when eccrine glands are less active, and then once every 1 or 2 weeks as maintenance therapy.[38] Atrophy of eccrine gland acini results. Use may lead to irritation.[38]

Iontophoresis

Iontophoresis is a procedure in which current is used to transport ions through the skin.[38] The mechanism by which iontophoresis acts to decrease sweating is not fully understood, although it is hypothesized that ion channels in eccrine glands are reversibly disrupted. In an iontophoretic treatment, a hyperhidrotic area of skin to be treated is covered with lukewarm tap water. Electrodes are then inserted into the water and a direct current delivered, usually at 8 to 20 amperages. The amperage is increased until a tingling sensation is experienced and applied for 10 to 20 minutes three to four times weekly. Improvement is typically noted in approximately 2 weeks and full improvement within 1 month. Maintenance treatments once or twice weekly can be helpful thereafter. Anticholinergic agents such as glycopyrronium bromide may be added to the tap water for refractory patients. Adverse effects may include irritation, hyperesthesia, and blisters.[38]

ANTIPRURITIC AGENTS (Table 222-3)

Antihistamines (See Chap. 230)

Doxepin

Menthol

Menthol is a highly lipid-soluble cyclic terpene alcohol, often used with camphor. It is derived from naturally occurring plant oils or prepared synthetically. Menthol is a counter-irritant that, by induction of a cool sensation, "crowds out" the sensation of itch. The cooling sensation may be the result of a direct interaction of menthol with cold receptors and/or nerve fibers.[43,44]

Phenol

Phenol in low concentrations (0.5 percent to 2.0 percent) acts as an antipruritic agent through its anesthetic effect. It is percutaneously absorbed and should be avoided in pregnant women and infants.[45]

Pramoxine Hydrochloride

Pramoxine hydrochloride is effective in cases of mild to moderate pruritus. As with other local anesthetics, it inhibits conduction of nerve impulses by altering the cell membrane permeability to ions. The onset of action of pramoxine products is 2 to 5 minutes.

ASTRINGENTS

In medical practice, astringents are any agent that causes contraction of the tissues, arrest of secretion, or control of bleeding. The U.S. Food and Drug Administration more strictly defines astringent drugs as "a drug product that is applied to the skin or mucous membranes for a local and limited protein coagulant effect."[46]

Aluminum Salts

Aluminum acetate tablets diluted 1:10 to 1:40 (Burow's solution) are an effective astringent and germicidal agent.

TABLE 222-4
Topical Keratolytic Agents

Agent	Dosage	Indications (Selected)	Side Effects/Comments	U.S. Food and Drug Administration (FDA) Pregnancy Category
α-Hydroxy acids	2%–20% as nonpeeling agent, > 20% as peeling agent	Photoaging, scaling, hyperkeratosis, acne, hyperpigmentation	Increased photosensitivity	Not contraindicated in pregnancy[61]
Propylene glycol	40%–60% under occlusion qhs; may be combined with salicylic acid (Keralyt gel) or Lactic acid (Epilyt); 2% vehicle in many preparations	Ichthyosis, hyperkeratosis, psoriasis	Enhances absorption of other topical agents; possible central nervous system effects	—
Salicylic acid	Scaly dermatoses: FDA-approved bid–qid at 1.8%–3.0%; callouses, corns, and warts: FDA-approved at 12%–40% for plaster vehicles, 12.0%–17.6% in collodion-like vehicles[62]	Hyperkeratosis, scaling	Salicylism (headache, drowsiness, and tinnitus). Maximum topical dose of 2 g/24 h	C
Urea	bid–qid in 10%–40% creams and lotions	Xerosis, pruritus, hyperkeratosis, eczema, ichthyosis, psoriasis, nail avulsion	Some patients experience burning; enhances absorption of other topical agents	C
Lactic acid (an α-hydroxy acid)	bid–qid in 5%–12% preparations	Ichthyosis, xerosis, eczema, photoaging	Hypothetical risk of metabolic acidosis	Not contraindicated in pregnancy[61]

Over-the-counter aluminum sulfate and calcium acetate (Domeboro) are available and, when dissolved in water, make a modified Burow's solution. These solutions may be used as wet dressings, compresses, or soaks.

Potassium Permanganate

Potassium permanganate is an oxidizing agent, astringent, antiseptic, and antifungal that may be used to clean or deodorize wounds. Solutions of 1:4000 to 1:16,000 may be used as wet compresses to reduce weeping or at 1:25,000 as a medicated bath. This agent may cause permanent staining of clothing and ceramics and temporary brown or bright purple staining of the skin, which may be removed with a weak solution of oxalic acid or sodium thiosulfate.

Silver Nitrate

Silver nitrate in 0.5 percent aqueous solution is an astringent and antimicrobial that is applied as a wet dressing in the treatment of infected eczema, gravitational ulcers, and other weeping and/or infected skin lesions caused by Gram-positive or Gram-negative bacteria. It is also available in a solid form that may be used as a hemostat. At low concentration (0.5 percent formulation, used clinically) it is bacteriostatic, while bactericidal at higher concentrations (10 percent). As methemoglobinemia has been noted secondary to topical treatment, methemoglobin levels should be followed with prolonged use.[47]

BLEACHING AGENTS

Hydroquinone

Usually used in concentrations of 2 percent to 5 percent, hydroquinone decreases pigmentation by inhibiting tyrosinase, thereby blocking the conversion of dopa to melanin.[48] It may also act by inhibiting DNA and RNA synthesis, degrading melanosomes, and destroying melanocytes. Adverse effects include irritant dermatitis, contact dermatitis, post-inflammatory pigmentation, and cutaneous ochronosis.

Tretinoin (Retinoic Acid)

Tretinoin is thought to inhibit transcription of tyrosinase, leading to decreased pigmentation.[48] It is typically used in concentrations of 0.05 percent to 0.1 percent to treat melasma.[48] Local adverse effects include erythema and desquamation, and post-inflammatory hyperpigmentation has been reported.

Azelaic Acid

Azelaic acid is hypothesized to mediate decreased pigmentation by inhibition of mitochondrial oxidoreductase activity, DNA synthesis, and tyrosinase. Treatment of melasma is typically with concentrations of 15 percent to 20 percent. Side effects include burning, itching, and erythema.

Monobenzyl Ether of Hydroquinone

Occasionally used to depigment skin in individuals with widespread vitiligo, monobenzyl ether of hydroquinone typically causes irreversible depigmentation via free-radical–mediated destruction of melanocytes and competitive inhibition of tyrosinase.[49]

KERATOLYTIC AGENTS (Table 222-4)

Keratolytics are agents that cause keratolysis, or peeling, of the epidermis. At low concentrations, most keratolytics act as humectants, or moisturizing agents.

α-Hydroxy Acids (See Chap. 252)

α-Hydroxy acids (lactic acid, glycolic acid, citric acid, glucuronic acid, and pyruvic acid) reduce the thickness of hyperkeratotic stratum corneum by an incompletely understood mechanism wherein the acids may directly solubilize the protein components of desmosomes or activate endogenous hydrolytic enzymes by changing the pH of the stratum corneum, resulting in keratolysis. Also, by diffusing into the stratum corneum and binding water, the acids act as humectants increasing the water content of the stratum corneum. This decreases the formation of dry scales on the skin surface and allows gentle rubbing of the skin during bathing to mechanically remove cornified tissue. The concentra-

tion of α-hydroxy acid, pH of the preparation, and composition of the base in which they are compounded are important in determining their efficacy. In general, more anhydrous preparations are less irritating, allowing higher concentrations of acid to be tolerated.

Propylene Glycol

Propylene glycol is a humectant, occlusive, and keratolytic agent. It is often combined with other medications to enhance their penetration. A combination of 20 percent propylene glycol with 5 percent lactic acid in a semi-occlusive cream base is used as a highly effective and well-tolerated keratolytic in patients with lamellar ichthyosis and may be used in various other hyperkeratotic diseases.[50]

Salicylic Acid

Salicylic acid has been used in concentrations ranging from 0.5 percent to 60 percent in almost any base. In concentrations of 3 percent to 6 percent, it causes shedding of scales by softening the stratum corneum, dissolving the intracellular matrix, and loosening connections between corneocytes.[51] In concentrations higher than 6 percent, salicylic acid is destructive to tissue. Salicylism has been reported with widespread and prolonged use, especially in children who should apply no more than 2 g (33 mL of a 6 percent solution) to their skin in a 24-hour period. Sensitization is rare, and irritation can be minimized if introduced at lower concentrations.

Urea

Urea is a humectant that is proteolytic at high concentrations. Urea has been added to some topical glucocorticoid preparations to possibly increase their penetration.[52] It is in preparations for dry skin and nail plate destruction.

Lactic Acid

Lactic acid is a humectant and keratolytic that is available at concentrations up to 12 percent. In addition to being a keratolytic, lactic acid increases ceramide production by keratinocytes improving water barrier function.[53]

PSORIASIS THERAPIES (See Chap. 18)

Anthralin

Calcipotriene (See Chap. 18)

A vitamin D analog, calcipotriol inhibits epidermal proliferation, induces epidermal differentiation, and exerts anti-inflammatory effects. Its effectiveness in psoriasis has been demonstrated in systematic reviews.[55,56] Hypercalcemia may occur if more than 100 g is used per week. It is applied initially twice daily, and maximal improvement can be expected within 6 to 8 weeks. Cutaneous irritation may occur in up to 20 percent of patients, particularly when used on the face or in intertriginous areas.

WART THERAPIES

Diphenylcyclopropenone

Diphenylcyclopropenone (DPCP), also known as *diphencyprone*, is a potent contact allergen used in the treatment of viral warts and alopecia areata. It is not available in pharmaceutic quality. Theories for its mechanism of action include alterations in cytokine levels, non-specific inflammation causing wart regression, and binding of DPCP to wart protein inducing a specific immune response.[57] Cross-sensitivity to other chemicals, apart from its precursor, α,α′-dibromodibenzylketone, has not been reported.[57] Many clinics recommend avoiding DPCP in children younger than 12 years of age, although children with alopecia areata less than 12 years old have been successfully treated with DPCP.[57]

Squaric Acid Dibutyl Ester

Squaric acid dibutyl ester is a potent topical sensitizer with a similar mechanism of action and use as DPCP. It requires refrigeration to maintain its potency.

Dinitrochlorobenzene

Dinitrochlorobenzene is a potent sensitizer with a similar mechanism of action and use as DPCP. Although dinitrochlorobenzene is mutagenic in vitro, there is no evidence of carcinogenicity in clinical practice.[57]

5-Fluorouracil (See Chap. 220)

Formaldehyde

Formaldehyde is a powerful disinfectant that causes anhidrosis, desiccation, and sometimes, hypersensitivity when applied to skin. It can cause hardening and fissuring of the skin, so normal surrounding skin should be protected from it by petrolatum, zinc paste, or meticulous application. Individuals with eczema or allergies should avoid formaldehyde as sensitization is problematic being that it is a ubiquitous component of many personal products.

Glutaraldehyde

Mono-, Di-, and Trichloroacetic Acids (See Chap. 252)

Monochloroacetic acid, dichloroacetic acid, and trichloroacetic acid in concentrations of 50 percent to 90 percent are all effective in the management of warts.[59] Trichloroacetic acid is also commonly used at lower concentrations (10 percent to 35 percent) for facial peels (see Chap. 252). Anal and vaginal lesions are occasionally treated with trichloroacetic acid, whereas monochloroacetic acid is most commonly used on plantar warts under salicylic acid plaster occlusion. The application needs to be repeated at 1- to 2-week intervals until complete resolution.

Podophyllin Resin (See Chap. 220)

Podofilox

Podofilox is podophyllotoxin, the active ingredient of podophyllin. It does not contain any of the ingredients responsible for the toxicity of podophyllin. It should not be used during pregnancy unless the potential benefit justifies the potential risk for the fetus.

Salicylic Acid

The effectiveness of salicylic acid in treating warts is thought to be related to keratolysis and local irritation of the skin in which the virus is present. Salicylic acid is the most established agent in terms of efficacy and safety in the treatment of viral warts.[60]

CHAPTER 223

Photoprotection and Sun Protective Agents

Henry W. Lim

With increased attention to physical fitness and outdoor recreational activities, daily exposure to sunlight is common. Although sun exposure may have beneficial effects such as mood elevation and vitamin D_3 photosynthesis, unwanted effects are well known. Acute effects of sun exposure include sunburn and delayed tanning. Chronic sun exposure is strongly associated with photoaging, actinic keratoses, and squamous cell carcinoma; intermittent sun exposure is associated with basal cell carcinoma and melanoma. Complete avoidance of sun exposure is neither necessary nor practical, nor will it be accepted by the general public. As such, behavioral modification of seeking shade during peak ultraviolet B (UVB) hours of 10:00 A.M. to 4:00 P.M. and the use of photoprotective measures, such as sunscreen, clothing, wide-brimmed hat, and sunglasses, have become the appropriate public health message to deliver. This chapter discusses the currently available, commonly used photoprotective measures.[1]

SUNSCREEN

History

In 1972, the U.S. Food and Drug Administration (FDA) re-classified sunscreens from cosmetics to over-the-counter (OTC) drugs, resulting in more stringent regulation. In 1990s, the need for protection against UVA, as well as against UVB, was recognized and led to development of UVA filters.

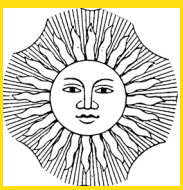
Sun Protection Factor

The sun protection factor (SPF) was first developed by an Austrian, Franz Greiter, in 1962 and was adopted by the FDA in 1978.[3] Current FDA guidelines specifically require that products be tested using a solar simulator with emission spectrum covering the wavelength range of 280 to 400 nm, and that the sunscreen product be applied at a concentration of 2 mg/cm^2.

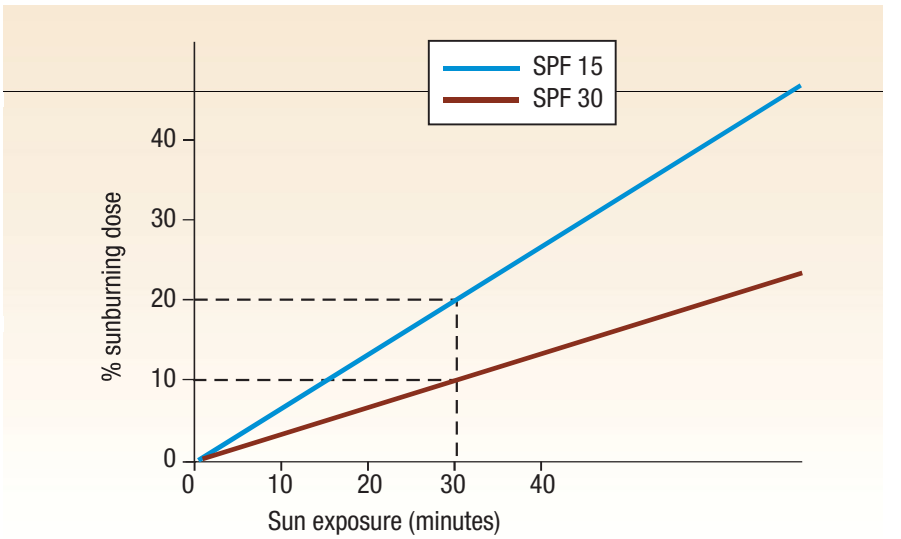
By definition, SPF is the ratio of minimal erythema dose (MED) of a subject's photoprotected skin over the MED of the unprotected skin. Because the end point is erythema, predominately an effect of UVB exposure, the SPF value is mostly a reflection of the protection against UVB radiation. If an individual develops slight erythema after 10 minutes of sun exposure, 30 minutes of unprotected sun exposure result in a 3 MED sunburn, that is, skin that 12 to 24 hours later is bright red and painful. In contrast, when wearing an SPF 15 or 30 sunscreen, the same 30-minute exposure would result in only 20 percent or 10 percent, respectively, of an MED, far less damage than required for induction of delayed erythema (Fig. 223-1).[4] Furthermore, with chronic exposure, the added protection from an SPF 30 sunscreen halves the cumulative UV damage compared to the SPF 15 sunscreen, even though both products prevent sunburn.

The concentration of sunscreen specified for SPF testing (2 mg/cm^2) is the equivalent of 1 oz (30 mL) of sunscreen to cover the entire body surface. Studies of the actual usage of sunscreen by individuals have consistently demonstrated that the amount of sunscreen applied is closer to 0.5 to 0.8 mg/cm^2, so that the actual in-use SPF is significantly lower then the label SPF.[5] The relationship is not linear, and an SPF 30 product (at 2 mg/cm^2) has an SPF of only 3 if applied at 0.5 mg/cm^2 (Fig. 223-2).[6] This situation causes many users to overestimate their degree of photoprotection and also

PHOTOPROTECTION AT A GLANCE



- Photoprotection measures include seeking shade during the peak ultraviolet (UV) B hours of 10 A.M. to 4 P.M. and the use of high sun protection factor broad-spectrum sunscreen, clothing, wide-brimmed hat, and sunglasses.
- New generation photostable UV filters are now available in Europe and many parts of the world and are beginning to enter the U.S. market.
- UV protection factor is a UV protection rating for fabrics. Several chemical treatments can increase the natural UV protection factor.
- Glass that filters out more than 99.9 percent of UV from 300 to 380 nm is now commercially available.
- Sunglass standards, mandatory in Australia and voluntary in the United States, specify a maximum percentage of light allowed to be transmitted and a minimum vertical dimension of sunglasses.



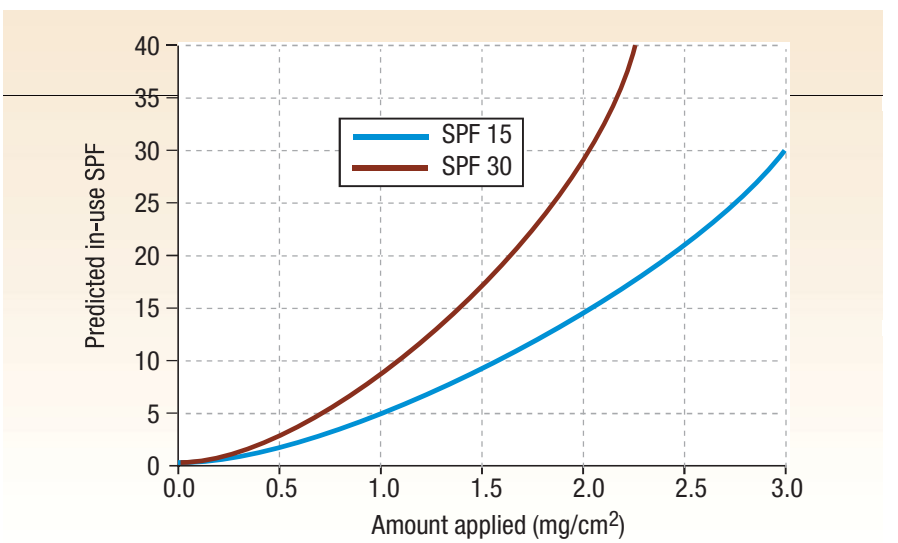
▲ **FIGURE 223-1** Effect of sun protection factor (SPF) 15 and SPF 30 sunscreens on cutaneous sunburning dose in an individual who develops minimal erythema after 10 minutes of sun exposure. After a 30-minute sun exposure, 20 percent of sunburning dose is achieved after the application of SPF 15 sunscreen; after the application of SPF 30 sunscreen, only 10 percent of sunburning dose reaches the skin.

confounds epidemiologic studies that rely on self-reported sunscreen use to judge the efficacy of sun protection in preventing, for example, skin cancer, including melanoma.

In the United States, the latest FDA sunscreen monograph (released May 1999) mandates that sunscreens that carry the label *water resistant* or *very water resistant* must maintain the label SPF value after two or four sequential immersions of the test subjects in water for 20 minutes, respectively.[7] The same monograph indicates that anti-aging claims are subjected to regulatory action as an unapproved new drug, and nonchemical and chemical-free claims are likely considered unacceptable.

Assessment of Ultraviolet A Protection

Although the SPF has now been accepted as the worldwide standard, there is as of yet no consensus on the optimal method of rating protection against UVA. However, several methods that have been published and are in use.[8–10] It should be noted that Australia and Japan have established their own official standards.



▲ **FIGURE 223-2** Relationship between the amount of sunscreen applied and the in-use sun protection factor (SPF). (Used with permission from J. F. Nash, Procter & Gamble, Cincinnati, OH.)

The Japanese Standard uses the persistent pigment darkening method. In that method, the dose of UVA required to induce persistent pigment darkening observed between 2 to 24 hours after exposure of sunscreen protected skin is compared to that of sunscreen-unprotected skin. The ratio is then expressed as UVA protection factor.[8] The Australian/New Zealand Standard does not require human subject testing and instead requires that an 8-μm layer of the product shall not transmit more than 10 percent of radiation of 320 to 360 nm, or a 20-μm layer of the product shall not transmit more than 1 percent of radiation of 320 to 360 nm. In addition, for products with broad-spectrum claim, their SPF should not be less than 4.

Currently, the European Union (EU) has developed guidelines for UVA protection that have been submitted to the European Committee for Standardization.[10] The guidelines include a UVA protection factor (as determined by persistent pigment darkening method) of $^1/_3$ of the UVB protection (i.e., SPF value) and a critical wavelength of 370 nm. The United States has not yet established a standard.

Immune Protection Factor

SPF for a sunscreen product correlates poorly with its ability to protect against immunosuppression.[11] This has resulted in the development of the concept of immune protection factor (IPF), quantifying the ability of sunscreen products to prevent immunosuppression.[12] Several different methods have been used, including contact sensitization, intradermal injection, and others, all of which are quite laborious and time consuming to perform. Until the time that a simple and reliable method can be easily performed in a large number of test subjects, it is unlikely that IPF will be used in any commercial products. Because IPF is better correlated with UVA protection than with SPF, it is likely that assessment of UVA protection would serve as a surrogate for IPF.

Ultraviolet Filters

There are three different nomenclatures used by the sunscreen industry and regulatory agencies around the world: International Nomenclature of Cosmetic Ingredients (INCI), United States Adopted Name (USAN), and trade name. USAN is the nomenclature used in the FDA Sunscreen monograph. For example, for a widely used UVA1 filter, the INCI name

TABLE 223-1
Ultraviolet (UV) Filters Listed in the U.S. Food and Drug Administration Sunscreen Monograph

U.S. Adopted Name[a]	International Nomenclature of Cosmetic Ingredients	λ_{max} (nm); or Absorption Range	Comment
Organic absorbers: UVB filters			
• PABA derivatives			
• PABA	PABA	283	Stains clothing. Not widely used.
• Padimate O	Ethylhexyl dimethyl PABA	311	Most commonly used PABA derivative. Photounstable.
• Cinnamates			
• Octinoxate	Ethylhexyl methoxycinnamate	311	Most widely used UVB filter. Photounstable.
• Cinoxate	Cinoxate	289	—
• Salicylates			
• Octisalate	Ethylhexyl salicylate	307	Weak UVB absorbers. Improves photostability of other filters.
• Homosalate	Homosalate	306	
• Trolamine salicylate	Time and Extend Application salicylate	260–355	Weak UVB absorbers. Good substantivity—used in water-resistant sunscreens and hair-care products.
• Others			
• Octocrylene	Octocrylene	303	Photostable. Improves photostability of photolabile filters.
• Ensulizole	Phenylbenzimidazole sulfonic acid	310	Water soluble. Enhances sun protection factor of the final product.
Organic absorbers: UVA filters			
• Benzophenones			
• Oxybenzone	Benzophenone-3	288,325	Most commonly used UVA filter. Most common cause of photoallergic contact dermatitis to UV filters.
• Sulisobenzone	Benzophenone-4	366	—
• Dioxybenzone	Benzophenone-8	352	—
• Others			
• Avobenzone	Butyl methoxydibenzoylmethane	360	Photounstable. Enhances the photodegradation of octinoxate.
• Meradimate	Menthyl anthranilate	340	A weak UVA filter. No sensitization reaction reported.
Inorganic absorbers			
• Titanium dioxide	Titanium dioxide	See below[b]	No report of sensitization reaction. Photostable; used to enhance photostability of the final product. Micronized zinc oxide has better UVA1 protection compared to microfine titanium dioxide. Micronized zinc oxide has lower refractive index compared to microfine titanium dioxide and thus appears less white. Commonly coated with dimethicone or silica to maintain effectiveness as sunscreen.
• Zinc oxide	Zinc oxide	See below[b]	

PABA = para-aminobenzoic acid.
[a]This is the name used by the U.S. Food and Drug Administration in the listing.
[b]λ_{max} ranges from visible to UVA to UVB range, depending on the particle size. As titanium dioxide is micronized (10–50 nm in diameter), λ_{max} shifts toward UVB; microfine zinc oxide maintains a flat absorption profile spanning from UVB to UVA.
Modified from Kullavanijaya P, Lim HW: Photoprotection. *J Am Acad Dermatol* **52**:937, 2005 and Department of Health and Human Services, Food and Drug Administration: Sunscreen drug products for over-the-counter human use; Final Monograph. *Federal Register* **64**: 27666, 1999.

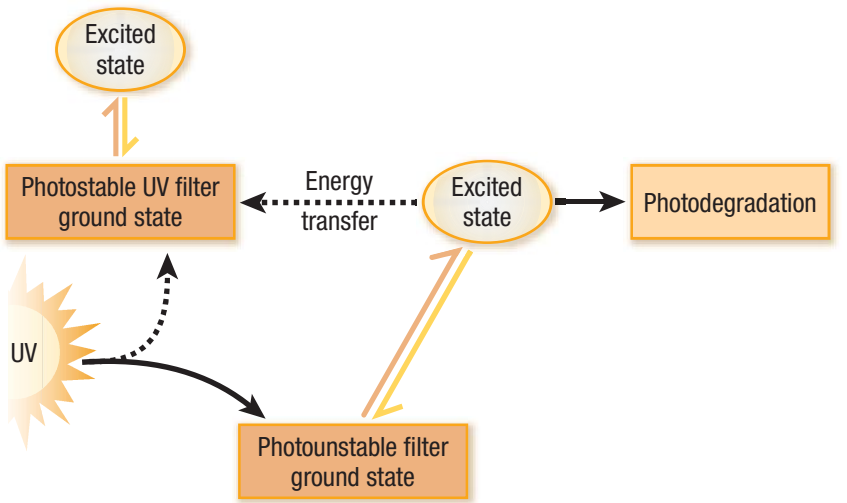
is butyl methoxydibenzoylmethane, the USAN is avobenzone, and a trade name is Parsol 1789. In this chapter, when available, the USAN nomenclature is used.

The term *sunblock* is commonly used to refer to sunscreens and their active ingredients, but it is a misnomer. The FDA Sunscreen monograph does not sanction the term. All sunscreen active ingredients are filters that absorb part of the incident UV radiation, but a portion of the radiation is always transmitted. Microfine inorganic filters additionally reflect and scatter UV radiation.

In the United States, all active sunscreen ingredients are regulated by the FDA as OTC drugs.[7] Only UV filters listed in the Sunscreen monograph issued by the FDA may be marketed in the United States (16 active ingredients; Table 223-1),[3] unless they have been approved as a final product by the FDA through the very expensive and demanding new drug application (NDA) process. The two latest UVA filters available in the U.S. market, avobenzone and ecamsule (Mexoryl SX™), both underwent the NDA process for their approval.

In 2002, the FDA instituted the Time and Extend Application (TEA) process as an alternate to filing the NDA.[13] With the TEA process, for the first time, data generated outside the United States can be used for the application, provided that the sunscreen product has been marketed for OTC purchase for a minimum of 5 years in the country where testing was performed. In the EU, South America, many Asian countries, and Africa, sunscreens are regulated as cosmetics, resulting in a simpler and more expeditious approval process compared to the United States, usually resulting in approval within 1 to 2 years of filing. In Australia and Japan, data on a complete formulation are required in addition to the data required by the EU approval process.

UV filters can be divided into two categories, *organic* and *inorganic*. These terms are recommended by FDA to replace the term *chemical* and *physical* filters, respectively. Organic filters can be subdivided further into UVB filters and UVA filters. The most widely used UVB filters worldwide is octinoxate (ethylhexyl methoxycinnamate), whereas the most widely used UVA filter is oxybenzone (benzophenone-3). Currently, unless products are approved as new drugs



▲ **FIGURE 223-3** Photostabilization of photounstable filter. Photostabilizing agent or photostable/ultraviolet (UV) filter absorbs a portion of incident photons, hence decreasing the number of photons absorbed by the photounstable filter. Photostabilizing agent/ultraviolet filter also serves as a receptor for energy transfer from the excited-state photounstable filter, facilitating the return of the latter to the ground state.

through the NDA process, the FDA guidelines do not allow avobenzone to be combined with inorganic filters (titanium dioxide, zinc oxide).

ULTRAVIOLET FILTERS AND PHOTOSTABILITY Avobenzone (butyl methoxydibenzoylmethane; Parsol 1789) is an excellent UVA1 filter but is photounstable and degrades during UV exposure. There are several other UV filters with this characteristic, including UVB filters padimate O [ethylhexyl dimethyl para-aminobenzoic acid (PABA)] and octinoxate (ethylhexyl methoxycinnamate).[14] It is possible to incorporate other agents to increase the photostability of the final product (Fig. 223-3). Most of these agents are photostable UV filters that absorb photons to minimize the effect on the photounstable UV filter; they also serve as receptor molecules for energy transfer (see Fig. 223-3).[5,15]

CURRENT STATUS OF ULTRAVIOLET FILTER APPROVAL

NEW DEVELOPMENTS

ULTRAVIOLET FILTERS AND PHOTOALLERGY Oxybenzone (benzophenone-3) is the most common cause of UV filter photoallergy. In contrast, the most widely used UVB filter, octinoxate (ethylhexyl methoxycinnamate), is rarely a photoallergen.[18] It should be noted that although UV filters are the most common cause of photoallergy in many studies in the United States and the United Kingdom, considering the number of individuals using sunscreens, the prevalence of photoallergy to UV filters is very low (well less than 1 percent). No photoallergy has been reported with inorganic UV filters (titanium dioxide and zinc oxide), the organic filter meradimate (mentyl anthranilate), or the new photostable organic filters listed in eTable 223-1.3.[19]

Sunscreen Use in Children

Because of the concern about percutaneous absorption of sunscreens, the 1999 FDA sunscreen monograph recommends that use of sunscreens in children under the age of 6 months should be decided by their physicians.[7] For this group of patients, it is prudent to use other means of photoprotection such as clothing.[5]

Controversies

MELANOMA It has been suggested that sunscreen use may be associated with an increased incidence of melanoma. However, meta-analysis of over 9000 patients from 11 case control studies and a quantitative review of all articles published from 1966 to 2003 that reported information on sunscreen use and melanoma in humans indicated that there is no creditable evidence that sunscreen use is a risk factor for the development of melanoma.[20,21]

VITAMIN D Another area of controversy is the concern that photoprotection may compromise health by decreasing serum vitamin D level, specifically the level of the highly variable "storage form" (25-OH-vitamin D) that is the precursor to the tightly regulated active form [1, 25-$(OH)_2$-vitamin D)]. Exposure to the UVB spectrum of sunlight converts 7-dehydrocholesterol in the skin to pre–vitamin D and thus allows its subsequent hydroxylation by the liver and kidney to the active form of the vitamin. Another source is dietary intake, although only a few naturally occurring foods contain a significant amount of vitamin D [e.g., salt water fish (herring, salmon, and sardines), cod liver oil, and egg yolk]. In the United States, milk, orange juice, margarine, butter, cereals, and chocolate mixes are fortified with vitamin D. Last, vitamin D supplements are readily available as vitamin D_3 (cholecalciferol, the form produced in skin) or more often as D_2 (ergocalciferol), which functions identically at the cellular level but may yield a lower serum level following a single bolus administration, compared to vitamin D_3.[22]

It has been demonstrated that application of an SPF 8 sunscreen blocks the increase in serum vitamin D level after exposure to a MED of simulated sunlight,[23] as expected. However, studies of more than 100 older individuals regularly using an SPF 17 sunscreen over a summer period to sufficiently decrease their risk of actinic keratoses revealed no difference in the increase in the serum vitamin D level compared to the placebo sunscreen group.[24] Even extreme photoprotection has been demonstrated to permit normal vitamin D levels. Specifically, a study of eight patients with xeroderma pigmentosum who scrupulously avoided all sun exposure, throughout a 7-year follow-up, showed serum vitamin D levels in the low normal range.[25] Furthermore, a 2-year follow-up study of individuals regularly using an SPF 15 sunscreen showed that although they had slightly lower serum vitamin D levels than controls who did not use sun protection, none of the subjects had abnormal parathyroid hormone or calcium levels,[26] which are markers of vitamin D insufficiency.

Epidemiologic data suggest that having high serum vitamin D levels decreases the risk of bone fractures, colorectal and pancreatic cancers, and multiple myeloma.[27,28] However, two randomized, prospective controlled studies involving over 36,000 post-menopausal women failed to show the beneficial effect of vitamin D supplementation over at least 7 years on bone fractures or on the development of colorectal cancer.[29,30] There

was also no correlation between these health outcomes and serum vitamin D levels or estimated sun exposure.[29,30] The benefit of high serum vitamin D levels, therefore, remains controversial.

Whatever the ideal vitamin D level is, the action spectrum for cutaneous vitamin D synthesis (i.e., UVB) is the same as for DNA damage and photocarcinogenesis. For those individuals who are concerned or are at risk for vitamin D insufficiency, a balanced diet and vitamin D supplementation appear to be the most appropriate steps to maintain adequate serum vitamin D level.[33,34] This recommendation applies to elderly individuals who are homebound or dark-skinned individuals with modest sun exposure,[31–34] as well as to children and young adults if there is any belief that their long-term health might benefit from having higher than currently recommended normal levels of vitamin D.

NANOPARTICLES Metal oxide inorganic UV filters, titanium dioxide and zinc oxide, have been widely used in microfine form. This is to minimize the reflection of visible light, thus enhancing the cosmesis of the final product. Nanoparticles are defined as particles less than 100 nm. Currently, 70 percent of sunscreens with titanium dioxide and 30 percent with zinc oxide use a nanoparticle form. In vitro, these particles can induce free radical formation in the presence of light, resulting in cell damage. Although the Australian Government Therapeutic Goods Administration concluded that the weight of current evidence shows that these particles remain on the surface of the skin,[35] continued monitoring is warranted.

TABLE 223-2
Factors Affecting Sun Protection of Garments

- Style of garment
- Number of layers
- Fabric thickness
- Type of fibers (polyester > wool, silk, nylon > cotton, rayon)
- Stretching
- Laundering
- Wetness
- Chemical treatments

Modified from Lim HW, Hönigsmann H: Photoprotection, in *Photodermatology*, edited by Lim HW, Hönigsmann H, Hawk JLM. New York, Marcel Dekker, 267, 2007.

GARMENTS

Clothing as a Photoprotective Measure

Clothing, including hats, is an integral part of photoprotection. Compared to sunscreens, they are easy to put on, durable, and a social necessity. However, in most cultures, there are body sites that are infrequently covered by clothing, such as the face, the V area of neck, and dorsal hands. During hot (and sunny) weather, garments tend to cover even less skin.

Ultraviolet Protection Factor

UV protection factor (UPF) is the in vitro measurement used in many countries, including the United States, to quantify the ability of fabrics to protect against UV. Because erythema is the factor considered, similar to the SPF, UPF is a better reflection of UVB than UVA protection.[36] In the United States, garments are classified as having good protection (UPF 15 to 24), very good protection (UPF 25 to 39), or excellent protection (UPF 40 to 50+).

As summarized in Table 223-2, several factors affect the UV protectiveness of garments.[1,37] UV absorbance of fibers is measured using fabrics that consist of a single type y fiber (e.g., 100 percent cotton, 100 percent polyester).[38] Polyester fibers are the best UV absorber, whereas cotton and rayon are the poorest. Laundering garments made from cotton or rayon increases the UPF because of shrinkage, causing a decrease in the porosity of the fabrics. Wetness decreases the UV-protection of a light colored (especially white) garment. This is because the protective effect of white cotton fabric is mainly due to light-scattering at the fiber/air interface: When wet, the fabric no longer scatters light, and the garment becomes more transparent to both UV and visible light. In contrast, dark-colored garments absorb light and thus do not become see-through or less UV protective when wet. Chemical treatments include the incorporation of UV absorbers to the fabrics during the manufacturing (mill finishing) process, addition of UV absorber as laundry additives, and addition of optical whitening agents widely incorporated in many laundry detergents in the United States and Europe. These latter agents absorb UV radiation at 360 nm and convert it to visible light wavelength of 430 nm; therefore, these agents decrease UV transmission through the fabric. The emission of visible light from the fabric makes the fabric look "brighter."

It is a common misperception that color of the fabric linearly correlates with the UPF. In experiments with cotton fabric with UPF of 4.1, red fabric with the same dye concentration had UPF of 41, 31, and 20, depending on the type of red dye used. A yellow fabric had UPF of 25, whereas a violet one had UPF of 24.[37]

TABLE 223-3
Types of Glass

TYPE	T_{VIS}	T_{UV}	COMMENT
Clear glass	> 90%	> 72%	
Reflective glass	19%	17%	Mirror-like appearance. Used in commercial buildings.
Low-emissivity glass	71%	20%	Reduces loss of generated heat and minimizes solar heat gain. Used in residential and commercial buildings.
Laminated glass	79%	< 1%	Two pieces of glass are bound to a plastic interlayer to prevent fragments from falling free if broken. Reduces sound transmission. Used for car windshields and in airports, museums, large public spaces.
Spectrally selective and UV-blocking insulating glass	69%	< 1%	Reduces heat loss/gain. Blocks > 99% of UV light (up to 380 nm).
ClimaGuard SPF glass	69%	< 0.1%	Reduces loss of generated heat and minimizes solar heat gain. Used in residential buildings.

SPF = sun protection factor; T_{UV} = transmission in the UV range (assessed from 300–380 nm); T_{vis} = transmission in the visible light range (assessed from 400–780 nm); UV = ultraviolet.
Modified from Tuchinda C, Srivannaboon S, Lim HW: Photoprotection by window glass, automobile glass and sunglasses. *J Am Acad Dermatol* **54**:845, 2006. Data provided by Guardian Industries Corp. (Auburn Hills, MI).

GLASS

Glass Used in Buildings and Cars

It is well known that UVB is effectively filtered by glass (reviewed in ref. 39). Many types of glass now also have very good UVA2 and UVA1 protection (up to 380 nm; Table 223-3). It should be noted that windshields of cars are made of laminated glass, which allows less than 1 percent of UV (300 to 380 nm) to pass through, whereas side and rear windows are usually made from non-laminated glass that allows a higher level of UVA transmission. This explains why common sites of involvement for patients with a photodermatosis are the side of the face and forearm closest to the side window of the car.[40]

Sunglasses

Australia has led the world in sunglass standards, developing the world's first national mandatory standard for sunglasses for general use in 1971; it was last revised in 2003 (AS/NZS 1067:2003).[41] The amount of light transmitted through the lens is called *luminous transmittance*; a lens with 20 percent luminous transmittance would allow 20 percent of the light to pass through. Lenses are grouped into five categories (0 to 4), ranging from fashion sunglasses (lens category 0) to special-purpose sunglasses for very high sun glare reduction (lens category 4). Category 0 lenses are allowed to have luminous transmission of 80 percent to 100 percent, whereas category 4, 3 percent to 8 percent. The Standard requires that the UVB transmittance be 5 percent of the luminous transmittance (i.e., if the luminous transmittance is 20 percent, then the allowed UVB transmittance is 5 percent of 20 percent, which is 1 percent); therefore, for lenses with luminous transmittance of 20 percent, this Standard mandates 99 percent of UVB to be blocked out. The UVA transmittance for lens categories 0 to 2 must be no more than the luminous transmittance, while for lens categories 3 and 4, 50 percent of the luminous transmittance. The Standard also mandates that the minimum vertical diameter for adult sunglasses is 28 mm, and for children, 24 mm.

The U.S. sunglass standard was first published in 1972 by the American National Standards Institute and last revised in 2001 (ANSI Z80.3-2001). However, unlike the Australian Standard, compliance with the U.S. Standard is voluntary and is not followed by all manufacturers[42]; therefore, consumers share the burden of responsibility. The U.S. Standard classified sunglasses as Normal Use (e.g., from home to the car to the office) or High or Prolonged Exposure (e.g., at the beach, fishing, skiing). Lenses are classified for intended function as special, dark, general purpose, or cosmetic tint. For example, for general purpose sunglasses, ANSI Z80.3 requires less than 1 percent of the wavelengths below 310 nm to be transmitted. No minimum vertical dimension of the sunglasses is stated in the U.S. Standard.

CHAPTER 224

Special Considerations for Topical Therapy of Ethnic Skin

Roopal V. Kundu

According to the U.S. 2000 census, 29 percent of the population is not white, and it is estimated that 50 percent will be of non-European descent by 2050.[1] Ethnic skin, also referred to as *skin of color*, is primarily composed of Fitzpatrick skin types V–VI and encompasses many racial and ethnic groups, including African Americans, Asians, and Hispanics. Persons of skin type IV may also fit into this category, encountering similar problems as those of darker skin types. Treatment of these patients requires knowledge of adverse reactions in darker skin and awareness of cultural issues specific to these patient populations.[2] The increased melanin in skin of patients with color is associated with increased susceptibility to post-inflammatory hyperpigmentation (Figs. 224-1 and 224-2) as well as hypo-

▲ **FIGURE 224-1** Acne with post-inflammatory hyperpigmentation on the cheek of an African American woman.

TOPICAL THERAPY OF ETHNIC SKIN

AT A GLANCE

- Ethnic skin, also known as *skin of color*, is primarily composed of Fitzpatrick skin phototypes V–VI.
- Skin with abundant epidermal melanin is susceptible to post-inflammatory hyperpigmentation.
- Optimal treatment requires knowledge of adverse reactions in darker skin and awareness of cultural issues specific to these patient populations.
- Hydroquinone is the mainstay of therapy for post-inflammatory hyperpigmentation.
- Strict photoprotection is essential.

pigmentation.[1] Post-inflammatory hyperpigmentation also occurs in Asian skin (Fig. 224-3). Therefore, any topical therapy that can alter pigmentation or irritate the skin needs to be used with caution. Optimal management of common conditions in patients with skin of color may include procedures like chemical peels[3] (see Chap. 252), Q-switched laser therapy[4] (see Chaps. 240 and 253), and microdermabrasion (see Chap. 252). However, this section will focus primarily on the topical treatment options available for dark skin.

▲ **FIGURE 224-2** Pseudofolliculitis barbae and lichen simplex chronicus with post-inflammatory hyperpigmentation on the chin and neck.

TOPICAL GLUCOCORTICOIDS

Topical corticosteroids are generally well tolerated in ethnically different skin. Low-potency steroids (i.e., classes V–VII) (see Chap. 216) infrequently cause hypopigmentation. In contrast, use of high-potency topical corticosteroids (i.e., classes I and II) can depigment normal skin within several weeks (Fig. 224-4). Fortunately, repigmentation of affected skin usually occurs if the topical steroid is discontinued promptly. Because of the known depigmenting effects, however, topical corticosteroids have been abused in some ethnic populations to lighten and bleach skin. Class I and II corticosteroids are frequently available over the counter in many ethnic stores in large metropolitan areas, despite U.S. Food and Drug Administration (FDA) regulations.

TOPICAL RETINOIDS (See Chap. 217)

Tretinoin

Irritation from topical retinoids, so-called *retinoid dermatitis*, can lead to post-inflammatory hyperpigmentation (Fig. 224-5). Hyperpigmentation can also occur without the clinical irritation because erythema is not as easily seen in darker-skinned individuals. However, when used carefully, topical tretinoin is well tolerated in patients with skin of color.[5–7] Topical retinoids may have an anti-inflammatory effect[8] and may be effective in the treatment of post-inflammatory hyperpigmentation,[5] photodamage,[6,9] melasma,[7,10] and acne. Any irritation associated with retinoids can be lessened by careful vehicle choice. A cream is preferred over a gel in skin of color because it is less drying. A microsponge delivery system of tretinoin is

▲ **FIGURE 224-3** Diffuse tinea corporis and post-inflammatory hyperpigmentation in an Asian American man. Large, arcuate, hyperpigmented patches with excoriations and erythema.

also now available in 0.1 percent and 0.04 percent concentrations and is less irritating to the skin than standard preparations. Patients should be instructed to apply the retinoid every other night for at least 2 weeks, then every night thereafter, as tolerated.

Adapalene

Adapalene is a synthetic retinoid that has selective affinity for retinoid X receptors β and γ.[11] Because the risk for retinoid dermatitis appears to be less than with tretinoin, adapalene may be especially effective in black[12] and Asian patients for the treatment of acne vulgaris.[13] Two different formulations, cream and gel, are available.

Tazarotene

Tazarotene is a synthetic retinoid whose metabolite selectively binds to retinoid X receptors β and γ.[14] Tazarotene is effective in psoriasis, acne vulgaris, and photodamaged skin. In darker racial ethnic groups, compared to vehicle, once-daily application of tazarotene produced a significantly greater reduction in acne lesions as well as improvement in post-inflammatory hyperpigmentation.[15] The drug was well tolerated, with limited dryness, erythema, or peeling. Topical tazarotene is available in cream and gel formulations.

Retinol

All-*trans*-retinol, or vitamin A_1, is metabolized to the active retinoid compound, tretinoin, in skin.[16] Retinol is used at a concentration of 0.1 percent to 1.0 percent

◀ **FIGURE 224-4** Hypopigmentation of the dorsal feet at sites of chronic topical corticosteroids application adjacent to sites of post-inflammatory hyperpigmentation secondary to dermatitis. (Used with permission from R. M. Halder, MD.)

in the United States in many over-the-counter products and is less irritating than tretinoin,[16] but has not been formally studied in darker-skinned individuals.

TOPICAL ANTIBIOTICS (See Chap. 218)

Topical antibiotics are well tolerated and effective in pigmented skin. Lotions and creams may be less irritating than gel formulations. However, gels are frequently associated with enhanced efficacy. Erythromycin and clindamycin are commonly used in the treatment of acne. Their anti-inflammatory effects may help reduce scarring and hyperpigmentation in skin of color. These agents are commonly used in combination with benzoyl peroxide to slow the development of antibiotic resistance.[17]

OTHER TOPICAL AND KERATOLYTIC AGENTS (See Chap. 222)

Acne Therapies (See Chap. 78)

Because an important goal in the treatment of acne in patients with darker skin is the prevention of post-inflammatory hyperpigmentation[18] (see Fig. 224-1), special attention should focus on the patient's propensity for developing irritation, especially when using combination therapy. Strategies to improve the tolerability of topical acne agents include initial low-dose therapy, slow upward titration, and alternate day dosing. Daily moisturization and avoidance of astringents, toners, and harsh soaps or cleansers are also important in preventing unwanted side effects of therapy.[19,20] Patients should be closely monitored for irritant dermatitis that may, itself, cause post-inflammatory hyperpigmentation. The influence of culture must also be recognized by discussing homeopathic practices, such as the common use of alcohol or witch hazel, both very drying, to cleanse the skin in the African American community.

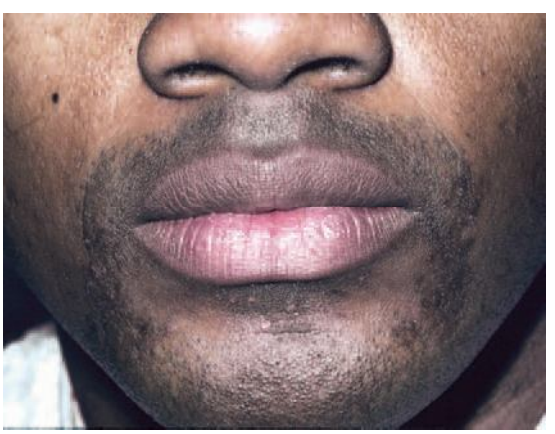
AZELAIC ACID Azelaic acid is a naturally occurring non-phenolic dicarboxylic acid isolated from cultures of *Pityrosporum ovale*. It is most commonly used in the treatment of acne, although its off-label uses include the treatment of hyperpigmentary disorders[21] such as melasma[22] and post-inflammatory hyperpigmentation. A 24-week study in South America found that a 20 percent concentration of azelaic acid was equivalent to 4 percent hydroquinone in the treatment of melasma.[23] However, azelaic acid may cause more local irritation than hydroquinone. Azelaic acid is available as a 15 percent gel and a 20 percent cream formulation.

BENZOYL PEROXIDE Benzoyl peroxide is commonly used for the treatment of acne vulgaris. Not only can it irritate the skin but it can also have a drying effect and can lead to either post-inflammatory hyperpigmentation or hypopigmentation in skin of color. It has been shown that a 2.5 percent concentration of benzoyl peroxide is as effective in lowering the inflammatory lesion count as 5 percent and 10 percent concentrations, while producing less erythema and desquamation.[24] Special attention should also be paid to the vehicle, which can also lead to drying and irritating effects. The alcohol-based gels seem to be the most irritating; therefore, starting with creams, lotions, or water-based gels is recommended.

Keratolytic Agents

α-HYDROXY ACIDS α-Hydroxy acids (lactic acid, glycolic acid, citric acid, glucuronic acid, and pyruvic acid) are penetration enhancers found in a variety of natural products, including cane sugar, fruits, and yogurt. These agents reduce the thickness of hyperkeratotic stratum corneum by reducing corneocyte adhesion and are effective in treatment of disorders of keratinization, photoaging, and hyperpigmentation. They are also used as cleansers, moisturizers, and chemical peeling agents.[25] Therapy should begin at low concentrations, with a gradual increase in the concentration and frequency in use of the formulation to limit side effects.

β-HYDROXY ACID Salicylic acid is the most commonly used β-hydroxy acid. Used at concentrations less than 6 percent, it causes dyshesion of the stratum corneum, and hence, reduces hyperkeratosis. At higher concentrations, salicylic acid is destructive to tissue. Salicylism has been reported with widespread prolonged topical use of salicylic acid, especially in children. Local irritation is common but can be minimized if the agent is introduced at lower concentrations. It is available commercially as a superficial peeling agent in solution form at concentrations of 20 percent and 30 percent. Salicylic acid chemical peels have been found to be safe and effective in darker-skinned patients.[26]



◀ **FIGURE 224-5** Perioral hyperpigmentation secondary to retinoid dermatitis in an African American man treated for acne. (Used with permission from R. M. Halder, MD and reproduced with permission from Halder RM: *Dermatology and Dermatologic Therapy of Pigmented Skins*. CRC Press, Boca Raton, 2006.)

DEPIGMENTING AGENTS

Hyperpigmentation can have a negative psychological impact on a patient's self-esteem, and treatment is therefore critical. Treating the underlying cause of post-inflammatory hyperpigmentation and strict photoprotection are important in preventing further dyschromia. Sun protection is not commonly a daily practice in persons of ethnically different skins. Moreover, in many cultures, a deep, rich tan is considered a symbol of health. It is essential to educate persons of skin of color about the exacerbating effect of sun exposure on dyschromia. Hydroquinone-based agents are currently the gold standard for treating hyperpigmentation. Other treatment modalities include cosmetic cover-up, topical retinoids, azelaic acid, chemical peels, and Q-switched laser therapy.[27,28] There are also several cosmetic "skin brightening agents" (non–U.S. FDA approved) commercially available in the United States, including arbutin, kojic acid, licorice extract, and niacinamide.[27–30]

Pigmentary, or melanin, incontinence is a unique form of post-inflammatory hyperpigmentation that is not responsive to topical depigmenting agents. Histologically, it is seen as an accumulation of melanin and melanophages in the upper dermis. Treatment modalities such as Q-switched laser therapy have been used with limited success.[4,31]

Hydroquinone

Hydroquinone is a hydroxyphenolic compound used extensively as a skin-bleaching agent. It inhibits the conversion of dihydroxyphenylalanine to melanin by inhibiting the tyrosinase enzyme.[30,32] Other possible mechanisms of action include the destruction of melanocytes, degradation of melanosomes, and the inhibition of the synthesis of DNA and RNA.[33] It is an effective depigmenting agent in many disorders of hyperpigmentation, including melasma and post-inflammatory hyperpigmentation, lentigines, and freckles. Hydroquinone has been combined with topical retinoids and glucocorticoids to enhance efficacy. Hydroquinone is available in over-the-counter concentrations (less than 2 percent) and prescription formulations (3 percent and 4 percent; Table 224-1). Higher concentrations (5 percent to 10 percent) may be compounded to treat severe post-inflammatory hyperpigmentation or melasma but may be unstable and irritating. Vitamin C, retinoids, and α-hydroxy acids (see α-Hydroxy Acids) may be used to increase penetration and enhance efficacy.

Adverse reactions include irritant and allergic contact dermatitis and nail discoloration. Post-inflammatory hyperpigmentation may occur from contact dermatitis. Reversible hypopigmentation in the form of a halo around the treated area of hyperpigmentation is often seen in dark-skinned patients. Individuals must be carefully counseled to use hydroquinone products twice daily only and to limit treatment to affected areas only to prevent this adverse effect.

Prolonged use of hydroquinone at concentrations greater than 6 percent over large body surface areas may cause local ochronosis.[34,35] It has been more commonly seen in African women[34,35] and infrequently reported in the United States. However, products with high concentrations of hydroquinone can be obtained illegally. Ochronosis is characterized by reticulated, sooty hyperpigmentation typically of the face and is often permanent. Treatment is difficult, but some cases may respond to topical retinoids and topical corticosteroids and/or a series of superficial salicylic acid chemical peels.[36] Permanent depigmentation due to melanocyte destruction may also occur. In

August 2006, the FDA proposed a rule change to restrict marketing of over-the-counter skin bleaching products containing hydroquinone. The FDA cited hydroquinone as having been shown to cause ochronosis after use of concentrations as low as 1 percent to 2 percent, along with new evidence of carcinogenicity in rats and mice. Therefore, the FDA stated that it cannot rule out the potential carcinogenic risk from topically applied hydroquinone in humans. The FDA proposed that hydroquinone in skin bleaching products be restricted to prescription use only, and users of such products should be closely monitored under medical supervision.

Combination Therapy

In 1975, Kligman and Willis reported efficacy of 5 percent hydroquinone, 0.1 percent tretinoin, and 0.1 percent dexamethasone in hydrophilic ointment in the treatment of melasma, ephelides, and post-inflammatory hyperpigmentation.[37] This combination was superior to the aforementioned agents used as monotherapy. In this formulation, tretinoin facilitates the epidermal penetration of hydroquinone and reduces corticosteroid-induced atrophy. The corticosteroid reduces the irritation caused by either hydroquinone and/or tretinoin. A newer formulation consisting of 4 percent hydroquinone, 0.05 percent tretinoin, and 0.01 percent fluocinolone acetonide in a cream base[38] is now available.

Monobenzylether of Hydroquinone

Monobenzylether of hydroquinone (monobenzone) is a topical phenolic agent that is typically used as a permanent depigmenting agent of noninvolved skin in patients with extensive vitiligo, resulting in greater than 50 percent pigment loss.[39,40] Areas of residual pigment can be treated with 10 percent to 20 percent monobenzone twice daily.[41] Depigmentation is usually achieved only after 6 months and usually requires periodic maintenance therapy to prevent repigmentation in areas of incomplete melanocyte destruction. Complications are frequent and include contact dermatitis, satellite depigmentation at distal sites, "consort vitiligo" in close contacts of the patient, and risk of sunburn after sun exposure.[40] Rigorous use of sun protection is mandatory. Patients must be able to accept the permanence of melanocyte loss.

Kojic Acid

Kojic acid [5-hydroxy-2-(hydroxyl methyl)-4-pyrone] is a naturally occurring hydrophilic fungal derivative produced by many species of *Acetobacter*, *Aspergillus,* and *Penicillium*[30] used in the treatment of hyperpigmentation disorders. Through its chelation of copper, it inhibits tyrosinase[9] with efficacy similar to 2 percent hydroquinone. Kojic acid has been used commonly in Japan, but the use has been limited because of its potential for causing contact dermatitis.[42] It is available over-the-counter in 2 percent to 4 percent concentrations.

Arbutin

Arbutin is a β-D-glucopyranoside derivative of hydroquinone. It is a naturally occurring, plant-derived compound that has been used for disorders of hyperpigmentation, although no controlled trials have been performed. It competitively inhibits tyrosinase and demonstrates a dose-dependent reduction in tyrosinase activity and melanin content in melanocytes. Higher concentrations may lead to paradoxical hyperpigmentation.[43] Arbutin is available in 3 percent concentrations in the United States.

Licorice Extract

Licorice extract is not currently available in the United States but is used in other parts of the world, particularly in Egypt. Its mechanism of action is similar to that of kojic acid. The main active component, the hydrophobic fraction glabridin, decreases tyrosinase activity.[44] It is available in cosmetic products only.[45]

Niacinamide

Niacinamide is the physiologically active amide of niacin (vitamin B_3), which may lighten skin by inhibiting melanosome transfer from melanocytes to keratinocytes.[46]

SECTION 37

SYSTEMIC THERAPY

CHAPTER 225

Systemic Glucocorticoids

Victoria P. Werth

Glucocorticoids (GCs) are a mainstay of dermatologic therapy because of their potent immunosuppressive and anti-inflammatory properties. In 1949, Hench and co-workers[1] described the beneficial effects of cortisone in patients with rheumatoid arthritis. By understanding the properties and mechanisms of action of GCs, one can maximize their efficacy and safety as therapeutic agents.

MECHANISM OF ACTION

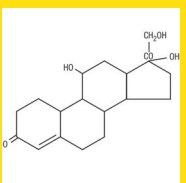
The major naturally occurring GC is cortisol (hydrocortisone). It is synthesized from cholesterol by the adrenal cortex. Normally, less than 5 percent of circulating cortisol is unbound; this free cortisol is the active therapeutic molecule. The remainder is inactive because it is bound to cortisol-binding globulin (also called *transcortin*) or to albumin. The daily secretion of cortisol ranges between 10 and 20 mg, with a diurnal peak around 8 A.M.[2] Cortisol has a plasma half-life of 90 minutes. It is metabolized primarily by the liver, although it exerts hormonal effects on virtually every tissue in the body. The metabolites are excreted by the kidney and the liver.

The mechanism of GC action involves passive diffusion of the GCs through the cell membrane, followed by binding to soluble receptor proteins in the cytoplasm.[3] This hormone-receptor complex then moves to the nucleus and regulates the transcription of a limited number of target genes. There are three main mechanisms of GC action. The first is direct effects on gene expression by the binding of GC receptors (GRs) to GC-responsive elements (GREs), leading to the induction of proteins like annexin I and MAPK phosphatase 1. Annexins reduce phospholipase A_2 activity, which reduces the release of arachidonic acid from membrane phospholipids,[4,5] limiting the formation of prostaglandins and leukotrienes.[6,7] The second mechanism is indirect effects on gene expression through the interactions of GRs with other transcription factors. Some of the most important appear to be inhibitory effects on the transcription factors activator protein 1 and nuclear factor κB, coupled with increased IκB, an inhibitor of nuclear factor κB.[8] This decreases the synthesis of a number of pro-inflammatory molecules, including cytokines, interleukins (ILs), adhesion molecules, and proteases. The third is GR-mediated effects on second messenger cascades through non-genomic pathways such as the PI3K-Akt-eNOS pathway.[9,10]

Human GR messenger RNA has alternative splice variants, GR-α and -β. The relative levels of these two variants influence the cell's sensitivity to GC, with higher levels of GR-β being one of many mechanisms leading to GC resistance,[10,11] as has been described in atopic dermatitis lesions infected with *Staphylococcus aureus*.

There is usually a delay in the onset of pharmacologic activity of GCs relative to their peak blood concentrations, which is probably consequent to altering the transcription of genes,[8] although some actions appear to be independent of transcription.[12] GCs may also exert their effects by non-genomic mechanisms such as membrane-bound receptors and/or physicochemical interactions with cellular membranes.[13] Some effects of GCs are too rapid to be mediated by genomic GC action.[14] This mechanism might explain additive benefits of very high-pulse GCs.

SYSTEMIC GLUCOCORTICOIDS AT A GLANCE



- Systemic glucocorticoids are potent immunosuppressives and anti-inflammatory agents frequently used for severe dermatologic diseases.
- Complications are increased with fluorinated compounds, higher doses, longer duration of therapy, and more frequent administration.
- Intralesional, intramuscular, intravenous, and oral routes of administration can be used.
- Careful monitoring of electrolytes, glucose, triglycerides, cholesterol, weight, fevers, skeletal or abdominal pain, bone density, and eyes are important.
- New treatments to prevent glucocorticoid-induced osteoporosis should be used in most patients.

The multiplicity of biologic effects produced by GCs emphasizes that currently there is no unifying hypothesis to explain the therapeutic efficacy of these extremely potent anti-inflammatory and immunosuppressive agents.

PHARMACOKINETICS

When hydrocortisone is given in moderate to high doses, its mineralocorticoid effects can be deleterious, and, thus, synthetic analogues of cortisol have been

▲ **FIGURE 225-1** **A.** Basic steroid skeleton. **B.** The structure of hydrocortisone (cortisol).

developed that have greater anti-inflammatory properties and less sodium retention. Small substitutions on the basic steroid structure of three hexanes and a pentane ring (Fig. 225-1; Table 225-1) account for the differences in plasma half-life and the relative anti-inflammatory and sodium-retaining potencies (Table 225-2). In general, most synthetic analogues bind less efficiently to cortisol-binding globulin (approximately 70 percent binding). This property may explain, in part, their tendency to cause side effects at lower dosages. The 11-β hydroxyl group in cortisol is essential for activity. Because cortisone and prednisone are 11-keto compounds, they are active only after being converted in the liver to the corresponding 11-β hydroxyl compounds (cortisol and prednisolone) (see Table 225-1). Patients with severe liver disease generally maintain their ability to convert the 11-keto compounds; nevertheless, some authorities suggest that only the converted active compounds should be administered to these patients.[27]

INDICATIONS

- Serious blistering diseases (pemphigus, bullous pemphigoid, cicatricial pemphigoid, linear immunoglobulin A bullous dermatoses, epidermolysis bullosa acquisita, herpes gestationis, erythema multiforme, toxic epidermal necrolysis)
- Connective-tissue diseases (dermatomyositis, systemic lupus erythematosus, mixed connective-tissue disease, eosinophilic fasciitis, relapsing polychondritis)
- Vasculitis

TABLE 225-1
Comparative Structures of Glucocorticoids

	Position				
	1–2	6	9	11	16
Cortisol	—	—	—	–OH	—
Cortisone	—	—	—	=O	—
Prednisone	Double bond	—	—	=O	—
Prednisolone	Double bond	—	—	–OH	—
Methylprednisolone	Double bond	CH3	—	–OH	—
Triamcinolone	Double bond	—	F	–OH	OH
Dexamethasone	Double bond	—	F	–OH	OH3

- Neutrophilic dermatoses (pyoderma gangrenosum, acute febrile neutrophilic dermatosis, Behçet disease)
- Sarcoidosis
- Type I reactive leprosy
- Problematic hemangiomas of infancy
- Kasabach-Merritt syndrome
- Panniculitis
- Urticaria/angioedema

Short courses of GCs may be used for severe dermatitis:

- Contact dermatitis
- Atopic dermatitis
- Photodermatitis
- Exfoliative dermatitis
- Erythrodermas

Low doses of GCs at bedtime if these conditions are unresponsive to more conservative therapy:

- Acne and hirsutism consequent to adrenogenital syndromes

The use of GCs is controversial in the treatment of erythema nodosum, lichen planus, cutaneous T-cell lymphoma, and discoid lupus erythematosus.

DOSING REGIMEN

Systemic GCs can be administered intralesionally, orally, intramuscularly, and intravenously. The route and regimen are determined by the nature and extent of the disease being treated.

Intralesional GC administration allows direct access to either a relatively few lesions or a particularly resistant lesion (see Chap. 216).

There are serious drawbacks to intramuscular administration because of erratic absorption and lack of daily control of the dose. Because Kenalog is longer acting than prednisone, there are more potential side effects, including increased hypothalamic-pituitary-adrenal (HPA) suppression and myopathy.

When oral GCs are prescribed, prednisone is most commonly selected. GCs are usually administered daily or every other day, although for acute disease split daily doses can be administered. The initial dose is most often daily to control the disease process and can range from 2.5 mg to several hundred milligrams daily. If used for less than 3 to 4 weeks, GC therapy can be stopped without tapering. The lowest possible dose of a short-acting agent every other morning minimizes side effects. Because cortisol levels peak around 8 A.M., the HPA axis is least suppressed with this morning dosage, and maximal feedback suppression of adrenocorticotropic hormone (ACTH) secretion by the pituitary is al-

TABLE 225-2
Glucocorticoids

	Equivalent Glucocorticoid Potency (mg)	Mineralocorticoid Potency	Plasma Half-Life (min)	Duration of Action (h)

Triamcinolone	4	0	300	24–36
Long-acting				
Dexamethasone	0.75	0	200	36–54

ready occurring. The low levels of GCs at night allow for normal secretion of ACTH. Low doses of prednisone (2.5 to 5.0 mg) at bedtime have been used to maximize adrenal suppression in cases of acne or hirsutism of adrenal origin.

Intravenous GCs are used in two situations. One is for stress coverage for patients who are acutely ill or are undergoing surgery and who have adrenal suppression from daily GC therapy. The other is for patients with certain diseases—such as resistant pyoderma gangrenosum, severe pemphigus, or bullous pemphigoid, serious systemic lupus erythematosus, or dermatomyositis—to gain rapid control of the disease and thus minimize the need for long-term, high-dose oral steroid therapy.[29] Methylprednisolone is used at a dose of 500 mg to 1 g daily because of its high potency and low sodium-retaining activity. Serious side effects associated with intravenous administration include anaphylactic reactions, seizures, arrhythmias, and sudden death. Other adverse reactions include hypotension, hypertension, hyperglycemia, electrolyte shifts, and acute psychosis. Slower administration over 2 to 3 hours has minimized many of the serious side effects, and as long as vital signs are determined frequently, patients without underlying renal or cardiac disease do not need to be treated in a monitored bed.[30] It is important to monitor serum electrolytes before and after pulse therapy, particularly when patients are on concomitant diuretic therapy. Recent studies suggest that doses that are less than the traditional high-dose (1 g methylprednisolone daily for 3 days) IV pulse therapy may be equally efficacious and safer.[31]

INITIATING THERAPY

Fundamental Principles

Before therapy with GCs is begun, the benefit that can realistically be expected should be weighed against the potential side effects. Alternative or adjunctive therapies should be considered, especially if long-term treatment is contemplated. Co-existing illnesses such as diabetes, hypertension, or osteoporosis need to be considered. The predisposition of the patient to side effects should be included in an assessment of risk.

Choosing among Glucocorticoids

A number of considerations influence the choice of GCs. First, a preparation with minimal mineralocorticoid effect is usually picked to decrease sodium retention. Second, the long-term oral use of prednisone or a similar drug, with an intermediate half-life and relatively weak steroid-receptor affinity, may reduce side effects. Long-term use of drugs such as dexamethasone, which has a longer half-life and high GR affinity, may produce more side effects without any better therapeutic effects. Third, if a patient does not respond to cortisone or prednisone, the substitution of the biologically active form, cortisol or prednisolone, should be considered. In general, even in severe liver disease, substitution has not proved to be very important. Fourth, methylprednisolone is used for pulse therapy because of its low sodium-retaining characteristics and high potency.

Evaluation before Treatment

To minimize potential problems, the baseline evaluation should include a personal and family history, with special attention to predisposition to diabetes, hypertension, hyperlipidemia, glaucoma, and associated diseases that could be affected by GC therapy. Baseline blood pressure and weight should be measured. If prolonged administration is anticipated, an eye examination and a purified protein derivative (PPD) test should be performed and an anergy panel applied. Examination for other covert infections should be based on history and physical examination. For instance, a stool culture for *Strongyloides* should be performed for immigrants from third-world countries and for Vietnam veterans.[32] If long-term administration of GCs is anticipated, baseline spinal bone-density measurement should be obtained by quantitative computed tomography, dual-photon absorptiometry, or dual-energy x-ray absorptiometry.[33]

MONITORING THERAPY

At follow-up visits, patients receiving chronic GC therapy should be questioned about polyuria, polydipsia, abdominal pain, fevers, sleep disturbances, and psychological effects. There may be serious effects on affect and even psychosis in patients with high doses of GCs. Weight and blood pressure should be monitored. Serum electrolytes, fasting blood sugar, and cholesterol and triglyceride levels should be measured on a regular basis. Stool should be examined for occult blood. Follow-up eye examinations should be performed with careful monitoring for the development of cataracts and glaucoma.

RISKS AND PRECAUTIONS (Table 225-3)

Diet

Diet should be low in calories, fat, and sodium, and high in protein, potassium, and calcium. Protein intake is important to reduce steroid-induced nitrogen wasting.[34] Use of alcohol, coffee, and nicotine should be minimized. Exercise should be encouraged.

Infections

Patients with a positive PPD should be given prophylaxis with isoniazid.[35] Anergic patients should have a baseline chest x-ray to search for evidence of previous tuberculosis. Fevers or focal findings should be evaluated with appropriate cultures and diagnostic approaches. Some advocate use of Bactrim prophylaxis (1 DS Bactrim 3 days a week) against *Pneumocystic carinii* when patients receive concomitant cytotoxic therapy.[27]

Gastrointestinal Complications

Although there is controversy about whether an increase in the incidence of peptic ulcer disease occurs in otherwise unaffected patients receiving GCs, there is almost a ninefold increase in patients taking both GCs and nonsteroidal anti-inflammatory agents.[36–38] In patients with two or more risk factors (such as those taking nonsteroidal anti-inflammatory medications, a previous history of peptic ulceration, advanced malignant disease, or a total dose of GCs more than 1000 mg), prophylaxis may be considered. Prophylaxis can include antacids, H_2-receptor blockers (cimetidine, ranitidine, nizatidine, or famotidine with the evening meal), or proton pump inhibitors (Prilosec or Prevacid).

Adrenal Suppression

Patients receiving daily GC therapy for longer than 3 to 4 weeks must be assumed to have adrenal suppression that requires tapering of the GCs to allow for recovery of the HPA axis. Tapering is best performed by switching from a single daily dose to alternate-day doses, followed by a gradual reduction of the amount of the drug. The daily dose is

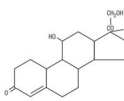

TABLE 225-3
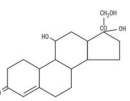
Prevention of Side Effects with Chronic (≥ 3 mo) Glucocorticoid Use

Side Effect	Preventative Measures
Hypertension	Blood pressure (baseline; repeat with each visit).
Weight gain	Weight (baseline; repeat with each visit).
Re-activation of infection	Purified protein derivative, anergy panel at baseline (can be done up to 12 days after starting prednisone). Hepatitis screen. Consider [illegible] pneumonia prophylaxis (Bactrim 1 DS three times a week).
Metabolic abnormalities	Electrolytes, lipids, glucose [baseline; repeat early after starting therapy; repeat annually; more frequent monitoring with known factors (e.g., diabetes, hyperlipidemias)].
Osteoporosis	Bone density (baseline; repeat annually is early bone prophylaxis done). Instruct about diet, exercise, other measures. Calcium and vitamin D supplementation. Start bisphosphonate for men, post-menopausal women. Evaluate post-menopausal women for hormone replacement therapy. Serum testosterone after treatment started in men; if low (< 300 ng/mL), check prostate specific antigen, prostate examination before starting testosterone replacement.
Eyes	
Cataracts	Slit-lamp examination (every 6–12 mo).
Glaucoma	Intraocular pressure examination (at 1 mo and every 6 mo).
Peptic ulceration	In patients with two or more risk factors, consider prophylaxis with and H_2-antagonist or proton pump inhibitor.
Suppression of hypothalamic-pituitary-adrenal axis	Single, early morning doses, preferably every other day. Check 8 A.M. serum cortisol before tapering prednisone < 3 mg/day. If < 10 μg/dL, repeat every 1–2 mo and maintain low prednisone dose until baseline cortisol adequate.



first gradually tapered to 40 or 50 mg of prednisone. Then, either the dose can be kept constant on 1 day and reduced on the alternate day by 5-mg decrements down to 5 mg/day, or, the steroid dose can be increased on 1 day and reduced by a similar amount on the alternate day. More studies are needed to determine optimal tapering schedules.[39]

After the prednisone dose is tapered to 5 mg on alternate days, the need for maintenance therapy must be assessed. The 8 A.M. plasma cortisol level is measured 4 weeks after the 5-mg dose has been reached. The morning dose of prednisone is held until the plasma cortisol level is determined. If the plasma cortisol level is less than 10 μg/dL, the alternate-day prednisone dose should be decreased by 1 mg every 1 to 2 weeks to a maintenance dose of 2 mg/day. Then the 8 A.M. plasma cortisol level should be rechecked every 2 months until it is greater than 10 μg/dL, at which point maintenance GCs can be terminated.[40] Recovery of the HPA axis can take longer than 9 months.[41] At that point and at any point when the patient is receiving tapering doses of steroids, a stress caused, for example, by trauma, surgery, diarrhea, or fever more than 38°C (101°F) can precipitate acute adrenal insufficiency related to an inadequate stress response. Patients should wear bracelets or carry cards indicating that they are receiving GCs. During such stressful situations, it is necessary to give high doses of GCs, generally 25 to 70 mg/day of prednisone or 100 to 300 mg/day of cortisol in divided doses.[42] Patients must be educated about the need for stress coverage.

The amount of GCs to give for coverage for surgery should probably be individualized to the severity of the operation. Minor operations lasting less than 1 hour are associated with, at most, 50 mg/day (12.5 mg prednisone) of cortisol in response to the surgery. Moderate to major surgeries are associated with the production of 75 to 200 mg/day of cortisol.[43,44] Thus, recent guidelines suggest that adrenally suppressed patients receive 25 mg of hydrocortisone equivalents for minor surgeries, 50 to 75 mg for moderate surgeries, and 100 to 150 mg for major surgery for 2 to 3 days, beginning when the patient is on call for surgery.[43] No trials have been done, and one recent study suggested even lower doses are adequate.[45]

In general, adrenal insufficiency resolves within 1 year of the termination of GC therapy. An ACTH stimulation test may be performed after maintenance GCs are terminated to assess adrenal reserve. This test is performed in the office by determining a baseline cortisol level, giving an intramuscular injection of 0.25 mg of cosyntropin, and measuring the serum cortisol level again 1 hour later.[40] The adrenal response is suppressed if the serum cortisol level fails to increase by at least 5 μg/dL to a stimulated value 60 minutes later of more than 20 μg/dL. If adequate adrenal response to stress is demonstrated, there is less concern about the endogenous cortisol response to stress.[27] However, such a response is not a guarantee of adequate adrenal reserves if severe stress occurs, and many physicians would choose routine stress coverage with GCs without performing an ACTH stimulation test.[46]

COMPLICATIONS

Complications associated with systemic GC therapy (Table 225-4)[47,48] increase with higher doses, longer duration of therapy, and more frequent administration. However, osteoporosis and cataracts develop with alternate-day dosing, and avascular necrosis (AVN) can be seen after only short courses of GCs.

Osteoporosis

Osteoporosis occurs in 40 percent of individuals treated with systemic GCs; it is especially prominent in children, adolescents, and post-menopausal women.[49] Approximately one-third of patients have evidence of vertebral fractures after 5 to 10 years of GC treatment, but this proportion is higher in post-menopausal women.[50,51] Bone loss occurs most rapidly in the first 6 months of GC use, but continues at a slower rate after that, with loss of 3 percent to 10 percent of bone per year in many patients.[49,52] Recent studies show that even low doses of prednisone (2.5 mg/day) adversely affect bone and increase vertebral and hip fractures.[53,54] Some of the bone loss may be reversible after GCs are stopped, at least in the young.[55]

Avascular Necrosis

AVN is manifested by pain and limitation of motion in one or more joints. There is intraosseous hypertension, leading to bone ischemia and necrosis.[59] It is likely

- Drug interactions (decreased anticoagulant effect of ethyl biscoumacetate)

Fibroblast inhibition
- Inhibition of wound healing
- Subcutaneous tissue atrophy (striae, purpura, ecchymoses)

Suppression of host defenses

Immunosuppression, anergy
- Effects on phagocyte kinetics and function
- Increased incidence of infections

that intraosseous lipocyte hypertrophy causes this intraosseous hypertension in persons taking GCs. In addition, GCs induce apoptosis of osteoblasts, likely contributing to AVN. Underlying diseases, such as systemic lupus erythematosus, increase the likelihood of steroid-induced AVN.[60] Studies suggest that many patients who develop AVN have either thrombophilia or hypofibrinolysis, which leads to thrombotic occlusion of venous outflow from the bone, decreased arterial perfusion, and subsequent infarction of bone.[61]

Atherosclerosis

GCs enhance many risk factors that are associated with atherosclerosis, including arterial hypertension, insulin resistance, glucose intolerance, hyperlipidemia, and central obesity. It is thus not surprising that patients taking GCs have an increased risk of atherosclerosis.[62] Patients with untreated Cushing disease have a four times higher mortality rate from cardiovascular complications, including coronary artery disease, congestive heart failure, and cardiac stroke.[63] The risk factors for atherosclerosis persist for at least 5 years after normalization of the serum cortisol level in Cushing disease, and similar findings may be true in those treated with chronic GCs.[64]

Suppression of the Hypothalamic-Pituitary-Adrenal Axis

The HPA axis is rapidly suppressed after the onset of GC therapy. However, if therapy is limited to 1 to 3 weeks, the recovery of the HPA axis is rapid. Longer daily GC therapy is associated with suppression of the HPA axis for up to 1 year after therapy is terminated.[41] Symptoms of adrenal suppression include lethargy, weakness, nausea, anorexia, fever, orthostatic hypotension, hypoglycemia, and weight loss.

There also exists a steroid withdrawal syndrome, in which patients experience symptoms of adrenal insufficiency despite having an apparently normal cortisol response to ACTH. Symptoms most commonly include anorexia, lethargy, malaise, nausea, weight loss, desquamation of the skin, headache, and fever. Less commonly, vomiting, myalgias, and arthralgias occur. These patients have adjusted to high levels of GCs, and symptoms disappear after the GCs are restarted. This problem can be treated by slower tapering of the GCs, often by 1 mg of prednisone every few weeks.[65]

Drug Interactions

GCs are associated with a number of important drug interactions. Drugs such as barbiturates, phenytoin, and rifampin, which induce hepatic microsomal enzymes, may accelerate the metabolism of GCs.[66] Drugs such as cholestyramine, colestipol, and antacids impair absorption of GCs. GCs reduce the serum salicylate level and necessitate a higher dose of warfarin (Coumadin) for anticoagulation.

Immunologic Side Effects

GCs impair delayed-type hypersensitivity reactions because of their inhibition of lymphocytes and monocytes. Prednisone at daily doses of 15 mg or more suppresses the response to tuberculin, although it takes an average of 13.6 days for oral prednisone at 40 mg/day to inhibit the response to tuberculin.[67] Thus, even in situations requiring immediate use of prednisone, it is possible to perform simultaneously a PPD test and an anergy panel. Overall, there is an increased incidence of infections attributable to both the GCs and the immunologic changes related to the underlying disease.[68]

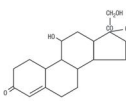
Concerns during Pregnancy and Lactation

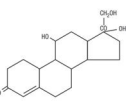
GCs cross the placenta, but they are not teratogenic. Exposed infants as well as breast-fed infants of mothers receiving GCs should be monitored for adrenal suppression and growth suppression. Based on animal experiments, there is some concern about the contribution of GCs to premature and low-birth-weight infants with respect to neurodevelopment.[69]

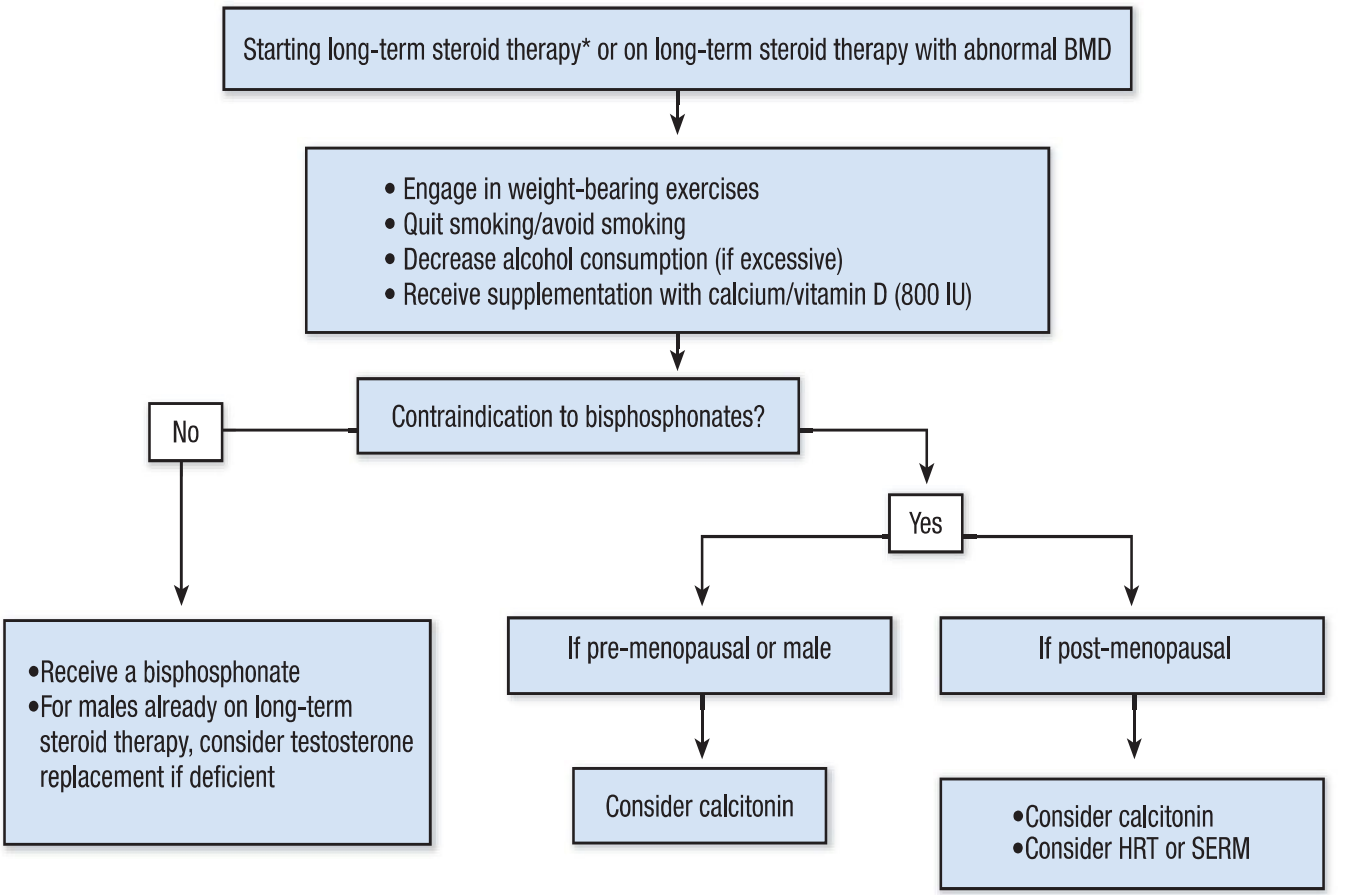
Concerns in the Pediatric Population

In the pediatric population, GCs cause growth retardation and early osteoporosis.[70] Growth retardation is caused by a direct action on cell metabolism, effects on calcium and phosphorus metabolism, and a decrease in growth hormone secretion, with inhibition of bone matrix formation. Growth retardation is not necessarily prevented by alternate-day GC regimens.[71] Recent studies show that human growth hormone replacement has a significant effect on growth, as well as a significant effect on lean body mass.[72]

Immunization with live vaccines can be done if the duration of GC use is less than 2 weeks at any dose, if the dose of GC is less than 2 mg/kg or 20 mg/day of any duration, and if long-term alternate-day treatment with short-acting preparations is done. Immunization with live vaccines should not be done for at least 3 months after receiving high doses of GCs (greater than 2 mg/kg or greater than 20 mg/day) for more than 2 weeks.[73]







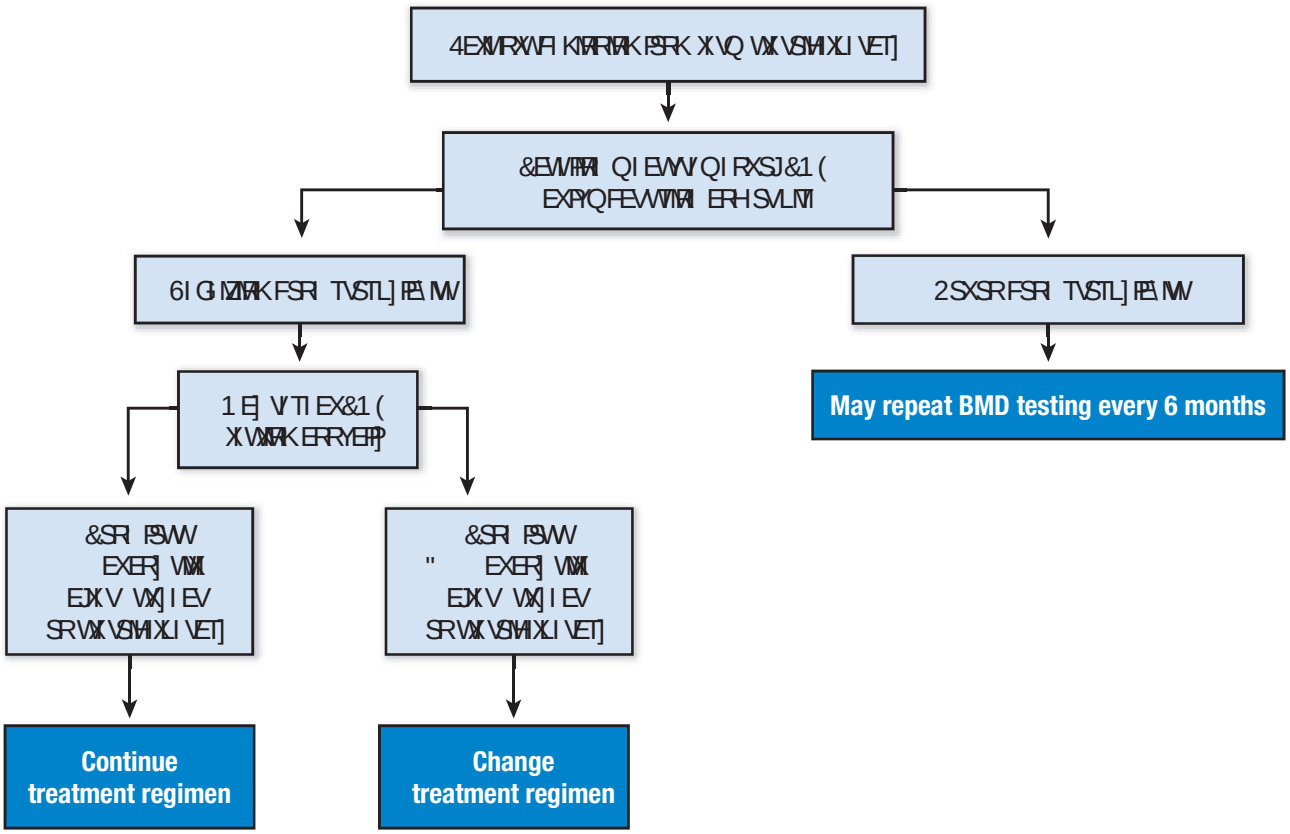
▲ **FIGURE 225-2** Treatment sequence for prevention and management of steroid-induced osteoporosis. *Long-term steroid therapy refers to ≥ 5 mg/day prednisone (or equivalent) for ≥ 3 months. BMD = bone mineral density; HRT = hormone replacement therapy; SERM = selective estrogen receptor modulator.

Management of Osteoporosis, Atherosclerosis, and Avascular Necrosis

OSTEOPOROSIS Attention to the prevention of osteoporosis is becoming increasingly important as newer therapies that may deter bone loss become available. Calcium and vitamin D supplements, sex hormone replacement, a weight-bearing exercise program, and sodium restriction are suitable first-line therapies.[74,75] Calcium and vitamin D together, but not calcium alone, preserve bone mass in patients receiving long-term treatment with GCs at an average of 15 mg/day.[74,76] Patients taking GCs should be given elemental calcium, 1500 mg/day, and vitamin D_2, 400 units twice daily. Activated forms (alfacalcidiol, 1 μg/day, or calcitriol, 0.5 to 1.0 μg/day) can be given, but more frequent monitoring is required for hypercalciuria and hypercalcemia. Patients with a history of renal stones should not receive supplemental calcium and vitamin D.[77,78] For patients receiving calcium and vitamin D_2, calcium levels should be measured in serum and in 24-hour urine collections every 3 months or whenever GC doses are substantially altered. If the urinary calcium level exceeds 250 to 350 mg/dL, the addition of 12.5 to 25.0 mg/day of thiazide reduces the renal excretion of calcium.[79] If thiazide is not added, calcium and vitamin D supplementation should be adjusted.

Current recommendations include baseline measurements of bone density and a sequential study to identify early those who are rapidly losing bone density.[74,113] Bone density is best measured in the lumbar spine in patients younger than 60 years of age and in the femoral neck in patients older than 60 years of age. All men and post-menopausal women in whom long-term GC treatment at 5 mg/day or more is being initiated or who have below-normal bone mineral density T-scores should receive bisphosphonates at the time GCs are prescribed. Bisphosphonates were found to be the most effective agents for managing GC-induced osteoporosis, and their efficacy was significantly enhanced when used in conjunction with vitamin D.[97,114] Pre-menopausal women treated with bisphosphonates should prevent pregnancy.[115] A decrease in bone mineral density of 5 percent or greater warrants changing or starting additional treatment strategies. Patients on chronic GCs benefit from bone prophylaxis, and physicians need to assure that patients receive appropriate treatment to prevent osteoporosis (Figs. 225-2 and 225-3).[116]

ATHEROSCLEROSIS Blood pressure, serum lipids, and glucose levels should be measured serially. Abnormalities should be treated with dietary manipulation and medication as necessary. Patients who smoke should be encouraged to stop. Female sex hormones protect against the development of atherosclerosis, and thus hormone replacement therapy for post-menopausal women on GCs makes sense. However, recent data suggest that women with established atherosclerosis actually do worse with hormone replacement therapy, and there was a 58 percent increase in coronary heart disease events in the first year after myocardial infarction in patients treated



▲ **FIGURE 225-3** Bone-density testing sequence based on recommendations from the American College of Rheumatology and Cohen and Adachi.[74,114] BMD = bone mineral density. with an estrogen/progestin combination. If patients develop increased levels of cholesterol or triglycerides while taking GCs, there are now good approaches to treatment, particularly with some of the newer statins, that impact on the development of atherosclerosis and prevent myocardial infarctions.

AVASCULAR NECROSIS Early detection is important because early intervention may prevent progression to degenerative joint disease requiring joint replacement. Twenty percent of patients with AVN have normal x-rays. Bone scan and magnetic resonance imaging are more sensitive techniques for evaluating AVN. Patients should be regularly questioned about pain and limitation of motion of joints. If abnormalities develop, an x-ray, bone scan, or magnetic resonance imaging should be ordered. If imaging shows AVN, an orthopedic surgeon skilled in early intervention with core decompression may be able to halt progression of the disease. Patients with AVN have an increased risk that other joints will be affected. The progression of AVN to destructive joint disease may require joint replacement surgery.[121]

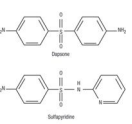
CHAPTER 226

Dapsone

Joni G. Sago
Russell P. Hall III

In the early 1950s, a sulfone named dapsone was shown to have dramatic efficacy in dermatitis herpetiformis[1] and has subsequently become first-line therapy for this disease. Since then, dapsone has been used in a wide variety of inflammatory skin conditions. Its appropriate use, however, requires an understanding of possible indications, usual dosing, proposed mechanisms of action, potential toxicities, and necessary monitoring. This chapter focuses on the use of dapsone in the treatment of inflammatory skin diseases.



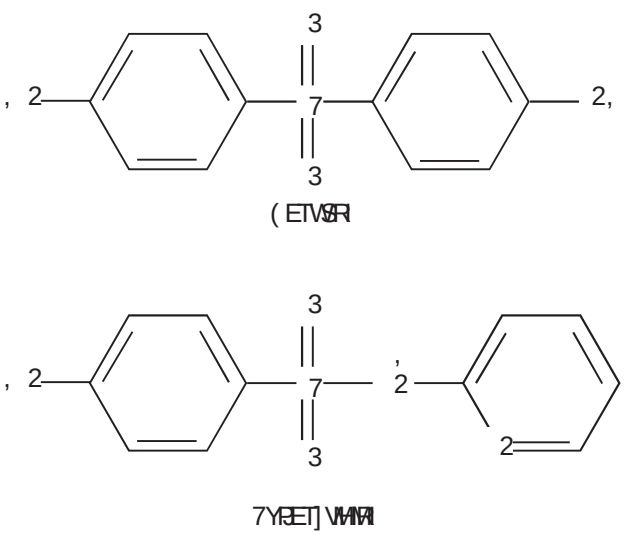
PHARMACOLOGY

Fig. 226-1 shows the chemical structure of dapsone [4,4′-diaminodiphenylsulfone]. Although dapsone is classified as a sulfonamide, cross-reactions rarely occur in sulfa-allergic patients. The most reliable confirmation of this lack of cross-reactivity has been noted when dapsone is used for 4R YQSG VWGEVRW pneumonia prophylaxis in sulfa-allergic acquired immunodeficiency syndrome patients. These patients have a low incidence of cross-reactivity (7 percent to 20 percent) and, if present, the cross-reactivity is usually mild and does not require dapsone discontinuation.[2,3] Sulfapyridine, a related compound, is available only on a compassionate-use basis from the manufacturer in the United States. It is thought to have similar mechanisms of action although with a reduced activity level and a lower incidence of toxicity than dapsone. Sulfapyridine may be useful, therefore, in patients who are unable to tolerate dapsone due to side effects.

Dapsone tablets are available in 25 mg and 100 mg sizes; therapeutic doses for various conditions range from 25 mg to approximately 400 mg. Dapsone is well absorbed from the gut with peak levels being reached 2 to 6 hours after a single dose. The steady-state half-life, however, is quite long (approximately 30 hours) due to enterohepatic re-circulation.[4] This allows for once-daily dosing and explains the utility of activated charcoal in reducing drug levels during accidental or intentional overdose.[5] Dapsone and its metabolites may be transmitted through human milk, and hemolysis has occurred in nursing infants.[6–8] No teratogenicity has been observed, although no controlled studies have been performed in humans and it is classified as pregnancy category C.[9,10]

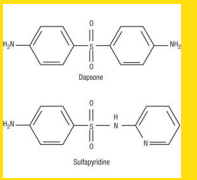
Dapsone is metabolized in the liver. The two major metabolic pathways involve acetylation and 2-hydroxylation (Fig. 226-2). Dapsone is acetylated polymorphically—that is, some patients rapidly acetylate dapsone to monoacetyldapsone (MADDS) whereas in others, this process occurs slowly. However, in all patients, MADDS is rapidly deacetylated. Thus, equilibrium between MADDS and dapsone is quickly reached and sustained. Dapsone's efficacy and half-life appear unrelated to the rate of acetylation[11,12]

The more clinically significant metabolic pathway involves hydroxylation of one of the amino groups by cytochrome 3A4 (and, to a lesser extent, 2C9) to form dapsone hydroxylamine, a potent oxidant that is important in the development of methemoglobinemia and hemolysis (see the section Adverse Effects).[13,14] Dapsone hydroxylamine is reduced back to the parent compound dapsone by cytochrome b_5 reductase (present in erythrocytes as methemoglobin reductase) as well as cytochrome b_5 and cytochrome P2D in hepatocytes.[15] Reduced enzyme levels have been detected in dapsone-treated patients who developed symptomatic methemoglobinemia; genetic variability in detoxifying enzymes may therefore explain patients' differential development of this side effect.[16] Although ex-

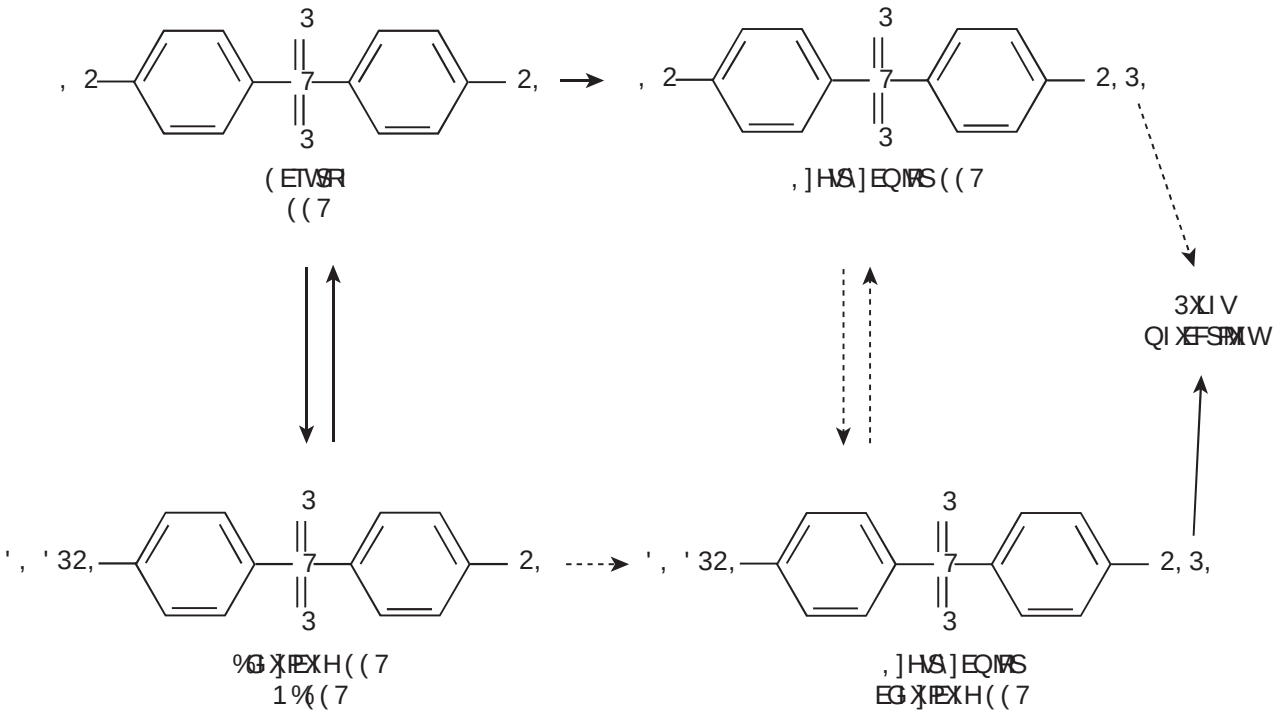


▲ **FIGURE 226-1** Chemical structure of dapsone and sulfapyridine.

DAPSONE AT A GLANCE



- Dapsone (4,4′-diaminodiphenylsulfone) is classified as sulfonamide but has unique pharmacologic properties.
- Diseases with consistent response to dapsone are dermatitis herpetiformis, erythema elevatum diutinum, linear immunoglobulin A dermatosis/chronic bullous disease of childhood and bullous eruption of systemic lupus erythematosus.
- Diseases with sporadic response to dapsone encompass a wide spectrum and are as diverse as collagen vascular/autoimmune diseases and acne. In these diseases, dapsone can be used as a corticosteroid sparing agent.
- A unifying feature of responsive diseases are neutrophilic and eosinophilic granulocytes.
- Dapsone is also effective in certain infections such as leprosy, actinomycetoma, or rhinosporidiosis
- Adverse effects are hemolysis and methemoglobulinemia. Glucose-6-phosphate dehydrogenase (G6PD) level should be obtained before beginning dapsone treatment. Dapsone should only be given with great caution to patients with G6PD deficiency.
- Other adverse effects are neuropathy, a mononucleosis-like hypersensitivity syndrome termed the *sulfone syndrome*, and agranulocytosis.



▲ **FIGURE 226-2** Dapsone metabolism in humans.

tensively hepatically metabolized, a small study of dapsone administration in cirrhotic patients demonstrated no need for dose adjustment.[17] However, caution is still recommended when using dapsone in patients with hepatic insufficiency.

Dapsone has been shown to interact with only a few other medications, including probenecid, which impairs its renal excretion[18]; rifampicin, which increases dapsone metabolism by upregulating the P_{450} system[19]; cimetidine and omeprazole, which block *N*-hydroxylation of dapsone[20,21]; and trimethoprim, which is associated with higher blood levels of dapsone.[22]

Dapsone and its metabolites are excreted by the kidneys, hence the recommendation to check a pre-treatment creatinine and avoid dapsone in patients with significant renal impairment.[4]

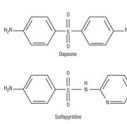
MECHANISM OF ACTION

Dapsone's interference with the folate biosynthetic pathway of bacteria accounts for its bacteriostatic effect; however, its mechanisms in inflammatory diseases are still incompletely characterized. Dapsone has several known effects on neutrophil function that may explain its utility in conditions with neutrophilic infiltrates. Dapsone inhibits chemotaxis of neutrophils to areas of inflammation. It also inhibits the paracrine production of inflammatory mediators and impairs the respiratory burst. Specifically, dapsone has been shown to inhibit neutrophil chemotaxis to the chemoattractant signals F-met-leu-phe[23] and LTB4.[24–26] Dapsone has also been found to inhibit migration and adherence of neutrophils to skin-localized immunoglobulin A[27] and interleukin-1–stimulated neutrophilic adherence to endothelium.[28] One study suggests that the mechanism behind impaired chemotaxis may be dapsone's interference with second-messenger signal transduction within neutrophils.[29] Additionally, dapsone has been shown to inhibit the release of IL-8, a potent neutrophil chemokine, from human keratinocytes that were incubated with antibodies to the human bullous pemphigoid 180-kd autoantigen.[30] Finally, dapsone has been shown to inhibit the myeloperoxidase-H_2O_2-halide–mediated cytotoxic system,[31,32] perhaps by inhibiting the calcium flux necessary for these events.[33]

INDICATIONS

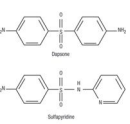
Since its introduction into clinical medicine, dapsone has had therapeutic trials and anecdotal successes in a multitude of diseases.[34,35] Diseases with consistent response to dapsone include: dermatitis herpetiformis,[36] erythema elevatum diutinum,[37] linear immunoglobulin A dermatosis/chronic bullous dermatosis of childhood,[38–40] and the bullous eruption of systemic lupus erythematosus.[41] Patients with these disorders achieve a clinical response within 24 to 48 hours and their condition flares over the same time course with drug withdrawal.

Other non-infectious conditions in which dapsone has found sporadic success can be divided into the following categories: collagen vascular diseases, acne and related disorders, autoimmune diseases, and inflammatory conditions. As a unifying feature, most of these diseases have granulocytes (neutrophils or eosinophils) as the predominant infiltrating cell. In most diseases, the neutrophils appear early in the pathologic process. The response to dapsone therapy is not as rapid, regular, or predictable in any of these diseases. However, dapsone may have a role as a second-line or steroid-sparing agent. Trials may need to last 3 to 6 months to ascertain effect. Collagen vascular diseases for which dapsone may be considered include rheumatoid arthritis[42] and rheumatoid papules[43]; relapsing polychondritis[44,45]; subacute cutaneous lupus erythematosus,[46] chronic cutaneous lupus,[46] and lupus profundus[47]; various vasculitides including cutaneous polyarteritis nodosa, Henoch-Schönlein purpura,[48] chronic leukocytoclastic vasculitis without internal organ involvement[49,50]; and Behçet syndrome.[51,52] A wide variety of autoimmune conditions have been treated with dapsone. More than 50 percent of steroid-resistant or steroid-dependent patients with idiopathic



thrombocytopenic purpura have been reported to respond to dapsone.[53,54] In bullous pemphigoid, some authors have advocated the use of dapsone as a regularly effective treatment,[55–57] whereas others have found its efficacy to be limited.[58] It may be useful in cicatricial (mucous membrane) pemphigoid,[59–61] particularly in the early inflammatory phase of ocular disease, sub-corneal pustular dermatosis,[62] pemphigus vulgaris,[63] pemphigus foliaceous,[64] and urticarial vasculitis.[50,65]

Acne vulgaris and acne conglobata have both been treated with dapsone, although the latter condition usually requires high doses and dapsone is not often necessary since the advent of systemic retinoids.[66]



Dapsone was originally developed as an antibiotic and some infections are still treated with dapsone. These include leprosy, malaria, actinomycetoma, rhinosporidiosis, and *P. carinii* pneumonia prophylaxis in sulfa-allergic, immunocompromised patients. Details of the use of dapsone for these indications are beyond the scope of this chapter.

A therapeutic clinical response to dapsone can usually be seen at doses ranging from 25–200 mg per day. Rarely, patients may require 300 mg per day before a response is seen. The initial dosage chosen should be between 50–100 mg per day in order to minimize potential pharmacologic adverse effects. If a therapeutic trial of dapsone is successful, the dose of dapsone should be decreased to a point at which lesions recur to be sure that the improvement was indeed due to dapsone and that there is a continuing need for the drug. An ongoing effort to reduce the dose of dapsone to the lowest effective dose is an important means to minimize potential adverse effects.

ADVERSE EFFECTS

Dapsone therapy, although generally well tolerated, has pharmacologic and idiosyncratic side effects. The pharmacologic side effects, hemolysis and methemoglobinemia, develop to some degree in all treated patients in a dose-dependent fashion. These adverse effects are caused by the hydroxylated metabolite, dapsone hydroxylamine, which is a potent oxidant.[13,14,85,86] Within erythrocytes, dapsone hydroxylamine generates reactive oxygen species, which oxidize oxyhemoglobin into methemoglobin and, through incompletely elucidated processes, also produces hemolysis. The hemolysis is accompanied by the appearance of Heinz bodies, which have been shown to be composed of oxidized hemoglobin. These Heinz bodies and hydroxylated metabolite/cellular protein adducts may label the red blood cells as senescent, targeting them for removal by the spleen.[86,87] Patients with G6PD deficiency have decreased amounts of reduced glutathione within their erythrocytes. Glutathione is responsible for reversing oxidative damage; thus, G6PD-deficient patients are less tolerant of pharmacologic oxidative stress and are at risk for substantial hemolysis.[88,89] G6PD deficiency should therefore be ruled out before initiating therapy. Hemolysis is more profound at the initiation of therapy and should be accompanied by a compensatory reticulocytosis; patients with pre-existing iron or B_{12}/folate deficiency may not be able to mount an appropriate compensatory reticulocytosis and are at greater risk for symptomatic drops in hemoglobin.[90] Thus, baseline anemias should be worked up before starting dapsone. Clinicians should also be aware that, after overdose, hemolysis may be delayed for as much as 9 days, so patients should be closely monitored.

Methemoglobinemia is another predictable consequence of dapsone therapy. It is again due to dapsone hydroxylamine's generation of reactive oxygen species leading to oxyhemoglobin oxidation.[13] Methemoglobin is unable to carry oxygen; signs and symptoms of methemoglobinemia are therefore those of poor oxygenation, including cyanosis, headache, shortness of breath, chest pain, and fatigue. Although some degree of methemoglobinemia occurs in most patients, symptomatic methemoglobinemia is rare. Patients with an inability to tolerate decreased oxygen carrying capacity, such as those with pre-existing cardiopulmonary disease or anemia, may develop symptoms at a lower percentage methemoglobin.[91] Pulse oximetry is a reasonable screening test for methemoglobinemia, as a normal value excludes significant methemoglobinemia. However, an abnormal value must be followed up with a direct methemoglobin determination, as degree of desaturation does not linearly correlate with methemoglobin levels.[92] Thus, a 90 percent saturation cannot be meant to imply 10 percent methemoglobin. Clinical cyanosis is a very insensitive indicator of methemoglobinemia and should not be relied on. In case of accidental or intentional overdose, intravenous methylene blue can be used to decrease the degree of methemoglobinemia.[95,96] Methylene blue is a co-factor for methemoglobin reductase after first being reduced by cellular stores of NADPH to leukomethylene blue. G6PD-deficient patients should not be given methylene blue, as they may have insufficient NADPH and unreduced methylene blue is its own direct hemolytic agent.

The other adverse effects of dapsone are idiosyncratic or allergic in nature (Table 226-1).[34–36] For instance, there are several neurologic sequelae that are rare, unpredictable side effects of dapsone. These include a distal motor neuropathy, occasionally with a sensory component.[97] This is reversible with dose decrease or discontinuation.[98] Checking patient distal motor strength at follow-up visits may alert the clinician to its development. Other neurologic side effects include the induction of acute psychosis.[99–101] Overdosage of dapsone has been reported to cause retinal damage; however, no evidence of ocular damage has been noted with therapeutic doses of dapsone.[102–104]

Dapsone is associated with a rare mononucleosis-like hypersensitivity syndrome termed the *sulfone syndrome*.[105–107] Like some anticonvulsants and other

Modified from Lang PG: Sulfones and sulfonamides in dermatology today. . %Q%GEH(IVQEXSR:479, 1979; Katz SI et al: Dermatitis herpetiformis: The skin and the gut. %6R-RXVR1IH93:857, 1980; and Alexander JO: Dermatitis herpetiformis, in 1ESV4VSFPQWR(IVQEXSPSK edited by Rook A. Philadelphia, Saunders, 1975, p 291.

medications that produce similar symptoms, the sulfone syndrome is best classified within the clinical spectra of drug-induced hypersensitivity syndromes. These are postulated to be due to drug-allergy–induced immunosuppression, leading to a re-activation of human herpesvirus 6 or other latent viruses.[108] This syndrome usually develops between 2 and 7 weeks after initiating dapsone and inevitably includes the triad of fever, rash, and hepatitis. The rash is most often an exfoliative dermatitis, but maculopapular and Stevens-Johnson–like lesions have occurred.[109] The hepatitis has a mixed hepatocellular and cholestatic picture with elevations in both transaminases and alkaline phosphatase.[110,111] Atypical lymphocytosis, anemia, itching, lymphadenopathy, and severe hypoalbuminemia with pedal edema and even anasarca, as well as renal hypersensitivity lymphocytic vasculitis, have also been reported to be part of this syndrome.[112,113]

Agranulocytosis is another rare, idiosyncratic side effect that has been estimated to occur in 0.2 percent to 0.4 percent of patients treated with dapsone.[115–118] If agranulocytosis occurs, its onset is almost always during the first 3 months of therapy.[115,116,119] Although usually reversible within days when patients stop therapy, it may be fatal due to superseding infection. Patients should be warned to seek medical care immediately if signs or symptoms of a serious infection develops during the first several months of therapy. Recombinant granulocyte colony stimulating factor has been used to produce a more rapid resolution of agranulocytosis.[120] Additionally, pure red cell aplasia has twice been reported with dapsone therapy.[121]

MONITORING OF DAPSONE THERAPY

Before therapy with dapsone is started, a history and physical examination to screen for pre-existing significant cardiopulmonary disease or peripheral neuropathy should be completed. Initial labs should include a complete blood cell count to determine baseline white blood cell count and hemoglobin. G6PD deficiency should be ruled out as should significant hepatic or renal dysfunction. After therapy has begun, a white blood cell count with differential and hemoglobin levels should be obtained weekly for the first month and then twice a month during the next 2 months. Thereafter, complete blood cell counts should be obtained periodically. Follow-up visits should include checking distal muscle strength, peripheral reflexes and reminding patients to not alter their dosage without physician guidance (to limit their risk for dose-dependent methemoglobinemia and hemolysis). Patients should also be told to carry a medication card so that in event of an emergency, treating physicians will know they are on a drug with hemolytic and methemoglobin-generating potential.

CHAPTER 227

Aminoquinolines

Jeffrey R. LaDuca
Anthony A. Gaspari

Antimalarial compounds have been used to treat skin diseases for over a century. Three compounds, chloroquine (CQ), hydroxychloroquine (HCQ), and quinacrine (QE), have been most studied. The 4-aminoquinolines are a family of compounds derived from quinine. CQ and HCQ, the principal members of this class of compounds, are the most often used for therapeutic use in dermatology. QE, classified as an acridine, has also been used in dermatologic therapy. Interestingly, the use of these medications for treatment and prophylaxis of malaria is waning due to increased resistance.

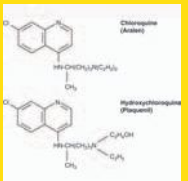
HISTORY

MECHANISM OF ACTION

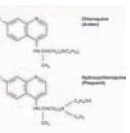
The precise mechanisms by which antimalarial compounds exert their actions are still unknown. However, several discrete mechanisms for each compound have been determined. In the treatment of malaria, aminoquinolines concentrate in the *Plasmodium* digestive vacuole and prevent polymerization of toxic heme released during proteolysis of hemoglobin.[11] Mechanisms by which these compounds influence skin diseases are varied.

CQ and HCQ are weak diprotic bases that are protonated, become trapped, and accumulate inside acidic vesicles such as lysosomes,[12] accounting for their effects in *Plasmodium*. HCQ induces signs of lysosomal membrane permeabilization and mitochondrial membrane permeabilization.[13] By raising intracellular vacuolar pH, antigen processing and presentation by dendritic cells may be downregulated. Inhibition of calcium signaling within the T cell may be involved.[14] Conversely, CQ has been more recently shown to enhance human $CD8^+$ T cell responses.[15] QE inhibits Na-K adenosine triphosphatase activity and stabilizes cell membranes.[16] It also concentrates in lysosomes. The effects are most appreciated in macrophages and phagocytizing cells where phagocytosis and chemotaxis are impaired.[17,18] Additionally, cellular enzymes and receptors dependent on lysosomes for function or activation are also affected, thus altering cells' responsiveness to mitogenic stimuli.[12]

AMINOQUINOLINES AT A GLANCE



- Aminoquinolines have been used in clinical medicine for more than a century, initially as antimalarial compounds.
- Multiple mechanisms of action, particularly impaired lysosomal acidification by antigen presenting cells, inhibition of natural killer and T-cell activation, and inhibition of lipid mediators of inflammation.
- Propensity for melanin pigment, absorb ultraviolet light, and exhibit photoprotective properties against ultraviolet-mediated injury of the skin.
- Aminoquinolines used to treat dermatologic conditions include hydroxychloroquine, chloroquine, and quinacrine.
- Hydroxychloroquine is the most commonly used aminoquinoline for skin conditions and is well studied for chronic cutaneous lupus erythematosus.
- Other aminoquinoline-responsive conditions: porphyria cutanea tarda, polymorphous light eruption, cutaneous sarcoidosis, dermatomyositis, and other conditions.
- Laboratory monitoring is mandatory during aminoquinoline therapy to detect hematologic abnormalities (hemolysis and drug-induced cytopenias), liver injury, and ophthalmologic toxicity (retinopathy).
- Children are especially susceptible to aminoquinoline toxicities, and lower doses must be used than in adults.
- Drug interactions are possible, and cigarette smoking decreases efficacy of aminoquinolines by inducing cytochrome P_{450} enzymes.



Antimalarials decrease T-cell release of interleukin (IL)-1, IL-6, tumor necrosis factor-α, and interferon-γ.[19,20] IL-1, IL-6, and tumor necrosis factor-α play a role in the hepatic production of acute-phase reactants.[21] Low concentrations of CQ and QE inhibit the pro–IL-6 stimulatory effect of cytosine-phosphorothiolated guanine-oligodeoxynucleotides on human peripheral blood mononuclear cells.[22,23] More recently, it has been found that CQ elevated the expression of B7-2 (CD86, a co-stimulatory protein) and intercellular adhesion molecule-1 (CD54, an adhesion molecule) in peripheral mononuclear cells, thus increasing IL-10–producing cells.[25] CQ has also been implicated in the inhibition of natural killer cell activity, decreased production of IL-2 from activated lymphocytes, and alteration of antigen-antibody complexes. QE also inhibits natural killer cells and blocks the primary proliferative response of cytotoxic T cells to allogeneic non–T-cell antigens.[21] Last, the arachidonic acid pathway is affected by antimalarial compounds. CQ inhibits phospholipase A_2 and C.[21] QE also inhibits phospholipase A_2 production[24,26] and increases nitric oxide release.[27] Thus prostaglandin, leukotriene, bradykinin, and histamine levels can all be decreased. QE antagonizes the generation of superoxide anions.[28]

The 4-aminoquinolines have an affinity for melanin pigment. In the epidermis (as well as retina), they bind in high concentrations. In the skin, CQ absorbs ultraviolet (UV) light in a concentration-dependent manner.[29] However, there is no effect on the minimum erythema dose.[30] Topical CQ applied before UV irradiation protects against UVB- and UVA-induced erythema.[31] QE has also been shown to inhibit photodynamic actions.[32] It has been proposed that the beneficial effect of the HCQ and CQ in various photodermatoses may result from the ability of these drugs to enhance the protective early limb of the UV response.[33]

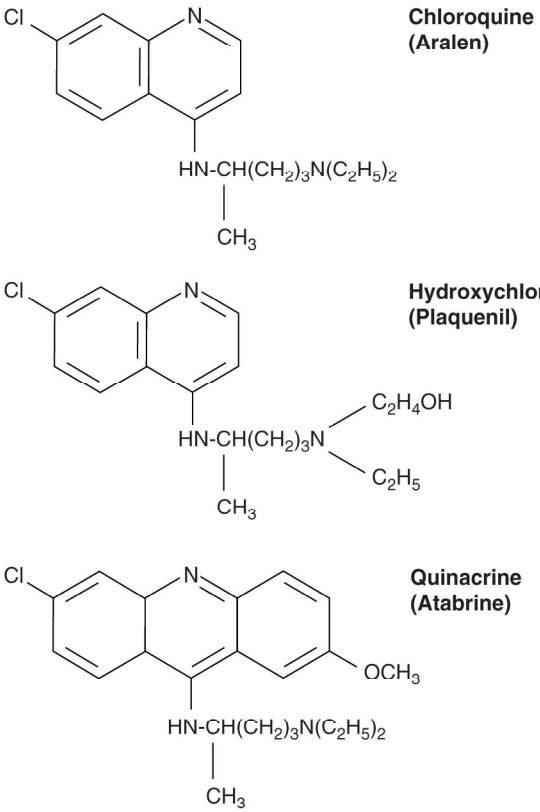
CQ and QE have been shown to bind cellular DNA by intercalation between base pairs, thus stabilizing the DNA.[34–36] RNA transcription and subsequent translation are inhibited. These may be the mechanisms by which these molecules effect lupus.[37]

Antimalarial compounds have been shown to exhibit myriad other effects. HCQ has been shown to improve lipid profiles.[38] Both CQ and HCQ improve glucose profiles[39,40] and inhibit platelet aggregation.[41] High doses of CQ may produce an antioxidant effect.[42] Through membrane stabilization, antimalarials can produce a local anesthetic effect.[12] In vitro, HCQ has been shown to induce apoptosis in B-chronic lymphocytic leukemia cells.[43] CQ, HCQ, and QE have all been shown to interfere with human immunodeficiency virus type 1 replication and function.[44–46]

PHARMACOKINETICS

The molecular structures of CQ, HCQ, and QE are closely related (Fig. 227-1). CQ and HCQ are 4-aminoquinolines. The addition of a benzene ring classifies QE as an acridine. The pharmacokinetics and pharmacology of these compounds are similar (Table 227-1). All are bitter, water-soluble, and readily absorbed from the gastrointestinal tract with relatively good bioavailability, achieving peak concentrations within hours. CQ and HCQ have large volumes of distribution and prolonged half-lives.[47] The volume of distribution for QE may be even larger than that of CQ and HCQ. QE is extensively bound to plasma proteins, whereas CQ and HCQ are only partially bound.[48–50] The half-life of QE is substantially less than the other compounds.[50] CQ is metabolized (dealkylated) in the liver by P_{450} enzymes into desethylchloroquine and bisdesethylchloroquine.[51] The metabolic fate of QE is less certain. CQ and its metabolites are stored in relatively high concentrations in the liver, spleen, lungs, adrenals, and melanin-containing cells.[52] Approximately 50 percent of CQ is eliminated by the kidneys unchanged.[48] HCQ is also metabolized in the liver (N-deethylation) into three chief metabolites: desethylhydroxychloroquine, desethylchloroquine, and bisdesethylchloroquine.[47] The parent compound and metabolites are taken up by lysosomes and concentrated in lysosome-rich tissues. Renal clearance accounts for approximately 15 percent to 25 percent of the total clearance.[53] The renal excretion of CQ, HCQ, and QE can be enhanced with acidification of the urine.[54] QE is excreted in urine, bile, sweat, and saliva.[50] Renal excretion only accounts for approximately 11 percent of its clearance. The highest tissue concentrations of QE are found in the liver and spleen.[52] Equivalent doses of these compounds are 250 mg of CQ, 400 mg of HCQ, and 100 mg of QE. Smoking may alter the pharmacokinetics of antimalarial compounds. Decreased absorption, increased plasma clearance, or induction of the cytochrome P_{450} system may be responsible.[55] Clinical evidence of decreased efficacy of these medications in smokers has been documented.[56]

Typical doses used in dermatology are 250 to 500 mg/day for CQ, 200 to 400 mg/day for HCQ, and 100 to 200 mg/day for QE. Evidence of efficacy is generally seen after 1 to 3 months of use, after which the dose may be tapered to a minimum effective dose. There is no cross-



◀ **FIGURE 227-1** Antimalarial drugs used in dermatology.

over reactivity between QE and CQ and HCQ.[57] Thus, its use in combination with HCQ and/or CQ has been deemed safe. In refractory skin conditions, addition of QE to HCQ or CQ has been deemed beneficial, and response may be seen in 6 to 8 weeks after the addition of QE.[58] If QE is added to CQ, the dose of CQ may need to be decreased to reduce potential for toxicity. Triquin, a combination of CQ (65 mg), HCQ (50 mg), and QE (25 mg) was used in the early 1970s. The concomitant use of CQ and HCQ increases the risk for retinopathy (see the section Complications). Thus, its use should be restricted to only severe cases. QE is not currently commercially available; production stopped in 1992. QE powder (veterinary grade, Sigma) can be put into capsules. Panorama Pharmacy in California, with an additional purification step, will prepare QE capsules.

INDICATIONS

The U.S. Food and Drug Administration–approved indications for CQ, HCQ, and QE are limited. As is often seen in dermatology, these compounds are frequently used in an off-label manner. Treatment of malaria is the only indication shared by all three drugs. HCQ has the most labeled uses, including rheumatoid arthritis, discoid lupus, and systemic lupus erythematosus. Extraintestinal amebiasis is the only other approved use for CQ. QE had been approved for treatment of giardiasis when it was manufactured. Experience with HCQ in dermatology is more extensive. Its lower incidence of ocular toxicity (see the section Complications) makes it a favored choice. In recalcitrant disease, CQ is often substituted with increased efficacy. The current difficulty in obtaining QE may account for the relatively fewer indications (Table 227-2).

Cutaneous Lupus Erythematosus (See Chap. 156)

Antimalarial drugs have been used for the cutaneous manifestations of lupus since the 1930s.[59] CQ and QE were found to also be effective in the treatment of cutaneous lupus during World War II.[10] Over 90 percent of patients receiving HCQ showed a benefit.[60] A double-blind trial of HCQ for discoid lupus showed a 70 percent response rate.[61] A review of 20 clinical trials involving the use of QE for cutaneous lupus showed a 73 percent response rate.[62] It is now accepted that antimalarial compounds are effective as steroid-sparing agents in the treatment of lupus erythematosus.[63,64] Antimalarials are typically used as steroid-sparing agents in patients whose symptoms cannot be controlled by topical steroids and sun protection. Widespread cutaneous lesions, hypertrophic

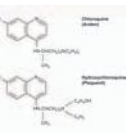
Equivalent doses	250 mg	400 mg	100 mg

and verrucous lesions, and long-standing discoid lesions do not respond as well. Systemic symptoms of fever or renal and hematologic abnormalities seen in systemic lupus erythematosus typically do not respond to antimalarial therapy. The onset of action for antimalarial therapy is 4 to 8 weeks. More rapid response may be seen with QE.[62] When HCQ is ineffective as a monotherapy, CQ may be more efficacious. The use of QE alone or in combination with either HCQ or CQ has also been suggested as providing a response in recalcitrant patients. Triquin, a combination of all three drugs, has been used for discoid lupus and cutaneous lupus erythematosus with success.



Polymorphous Light Eruption (See Chap. 90)

Polymorphous light eruption is an inflammatory reaction seen on sun exposed skin. IL-1, -6, and -8 may play a role in the inflammatory process.[65] Chloroquines decrease IL-1 and IL-6 and release and absorb UVA light. These drugs have been used for polymorphous light eruption for several years.[66,67] More recently, placebo-controlled trials have proven efficacy for this indication.[68] HCQ at doses of 200 to 400 mg/day is effective. Topical sunscreens should also be used in conjunction with antimalarial therapy. In northern climates, discontinuation of therapy during winter months may decrease cumulative side effects of antimalarial therapy.

Porphyria Cutanea Tarda (See Chap. 132)

The first reported case of CQ therapy for porphyria cutanea tarda (PCT) was published in 1957.[69] Phlebotomy remains the principal treatment for PCT after exacerbating factors are identified and removed. Antimalarial therapy is used with phlebotomy as an adjuvant therapy or when phlebotomy is not possible. Chloroquines inhibit porphyrin synthesis and mobilize lysosomal stores of porphyrins, allowing for the formation of water-soluble complexes, which are then excreted by the kidneys.[70] Hepatotoxicity is a concern, and liver enzymes should be followed closely during therapy. Headache, nausea, fever, elevated transaminases, and urinary excretion of porphyrins occur 3 to 4 days after initiation of therapy with CQ at 250 mg/day.[71] Prolonged remissions have been reported with high doses of HCQ (250 mg tid) for short courses.[72] However, marked increases in liver transaminases required the hospitalization of all patients in this study during the initiation of therapy. Low-dose CQ therapy (125 mg biw for 2 weeks followed by 250 mg biw thereafter) gave a 94 percent response rate in one study of 53 patients.[73] Alternatively, HCQ used at 100 mg tiw for a month, then 200 mg tiw for a month, then advanced to 200 mg qd has been proposed.[74] These lower dosing schedules seem to alleviate the severe hepatotoxicity. A combination of phlebotomy before initiation of CQ therapy may also reduce the severity of hepatotoxicity.[75]

Sarcoidosis (See Chap. 153)

Antimalarial therapy for cutaneous manifestation of sarcoidosis was first described nearly half a century ago. A 1996 review of the subject concluded that antimalarials were highly effective, with greater than 70 percent response rate.[76] Two to three mg/kg/day of HCQ has been reported as being effective in 12 of 17 patients treated.[77] CQ therapy initiated at 500 mg/day for 2 weeks, then a maintenance dose of 250 mg/day has been described as safe and effective.[78] Therapy may also be effective for associated hypercalcemia. Another granulomatous disease, generalized granuloma annulare, has also been reported to respond to HCQ.[79]

Cutaneous Dermatomyositis (See Chap. 157)

Cutaneous symptoms of dermatomyositis may be managed by antimalarial therapy. Monotherapy with either HCQ 200 mg bid (less than 6.5 mg/kg/day) or CQ 250 mg qd (less than 3.5 mg/kg/day) is often adequate to control skin manifestations. The addition of QE to either HCQ or CQ has been shown beneficial in patients with recalcitrant skin disease.[58]

DOSING REGIMEN

Use of antimalarial compounds in dermatology is varied. Each disease state is treated differently with special concerns pertaining to the disease entity. As such, dosing for each condition is dependent on the underlying pathology. Usual starting doses for HCQ are between 200 and 400 mg/day. Equivalent dosing for CQ is 250 to 500 mg/day, and for QE, 100 to 200 mg/day. However, initiation of therapy and maintenance dosing may be different for each disease. Combination therapy with these medications also alters the dosing.

INITIATING THERAPY

Uses of antimalarial drugs in dermatology are varied. Several dermatoses have been successfully treated with these molecules (see the section Indications). Different therapeutic strategies have been used, depending on the given disease state. Nonetheless, many principles govern the initiation of therapy. The correct diagnosis of disease is essential. Biopsies and blood laboratories should be used to confirm the patient's diagnosis, as well as the presence of an antimalarial-responsive dermatosis (see Table 227-2). After the diagnosis is established, one should determine whether the patient is able to tolerate the medication and need for monitoring. Hematologic and metabolic side effects have been reported with the use of these medications, and routine monitoring of laboratory values is necessary. Patients who are deficient in the glucose-6-phosphate dehydrogenase (G6PD) enzyme are more prone to a hemolytic anemia. Thus, baseline evaluation of G6PD enzyme, complete blood cell count, and serum chemistry panel should be performed before initiation of therapy in all patients. Ocular toxicity is a concern with HCQ and CQ. Baseline evaluation by an ophthalmologist is necessary. Slit-lamp assessment, funduscopic examination, and assessment of visual acuity and fields should be included.

MONITORING THERAPY

Monitoring antimalarial therapy should be done in all cases. Laboratory monitoring should include a complete blood count performed monthly for 3 months to ensure that hemolytic (or, less commonly, aplastic) anemia is not occurring. Thereafter, quarterly to semi-annual complete blood counts should be obtained. A comprehensive metabolic panel should be checked after the first month of therapy and then again after 3 months. Special attention should be paid to liver enzymes, particularly in patients on other hepatotoxic medications and in cases of porphyria. Quarterly to semi-annual chemistries should be followed while on maintenance therapy.

Monitoring for ocular toxicity is debated. American guidelines include a

baseline slit-lamp, funduscopic, visual field, and acuity examination by an ophthalmologist. Periodic eye examinations during the first 5 years of use should be performed, based on the age of the patients, as if they were not being treated with an antimalarial agent. As no patient with normal renal function treated with HCQ at doses less than 6.5 mg/kg/day developed retinal toxicity in the first 6 years, the need for scheduled semiannual or annual examinations is not deemed necessary. After 5 years, annual examinations are recommended.[80] Canadian and British guidelines suggest that the baseline assessment before initiation of therapy include asking about visual impairment and recording the best corrected visual acuity. Thereafter, yearly assessments should be made.[81,82] In practice it has been shown that even these guidelines are not routinely followed.[83] As the risk of irreversible ocular toxicity appears low, there has been a call to revise even these guidelines.[84]

COMPLICATIONS

Most side effects of antimalarial therapy are reversible (Table 227-3). Decreased dosing or drug withdrawal may completely alleviate a majority of side effects encountered with these drugs. Without proper monitoring, however, these drugs have the potential for serious and permanent side effects.[84a]

Gastrointestinal complaints of anorexia, nausea, vomiting, diarrhea, and weight loss are most commonly encountered side effects (10 percent for HCQ; 20 percent for CQ; 30 percent for QE).[85] Acute symptoms from high doses of CQ and HCQ include blurred vision, cardiovascular toxicities, hypotension, neurotoxicity, and respiratory or cardiac arrest.[48,49] In children, as little as 0.75 g of CQ can be fatal (2.25 to 3.0 g in adults).[86] Lethal doses of HCQ are considered to be in a similar range.[48,49] Several cases of overdose have been reported. Management of overdose consists of gastric lavage, ventilation, and inotropic support.[87–91] As little as one or two tablets of CQ or HCQ can be dangerous in children. Appropriate monitoring is necessary after accidental ingestion.[92] A lethal dose of QE is not determined.

Patients with G6PD deficiencies are susceptible to CQ- and HCQ-induced hemolytic anemia, although rarely in therapeutic ranges. Aplastic anemia with QE[93,94] and agranulocytosis with CQ[95] have also been reported.

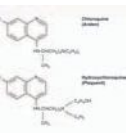
Cutaneous adverse effects can be seen with antimalarial therapy. Exacerbation of pre-existing psoriasis in as many as 18 percent of patients with psoriasis has been documented with the use of antimalarial drugs.[96] CQ is responsible for most psoriatic flare-ups, and QE is more likely to induce exfoliative erythroderma. HCQ is much less likely to exacerbate psoriasis.[97] It has never been convincingly demonstrated that the apparent exacerbation of psoriasis represents an adverse drug–disease interaction. These flares in psoriasis may represent an allergic reaction to antimalarial compounds. In the general population, incidence of pruritus and rashes secondary to antimalarial use is reported to be 10 percent to 20 percent.[98] Dose-related QE-induced drug eruptions were reported during World War II. One in 2000 soldiers taking 100 mg qd reported a reaction, whereas 1 in 600 soldiers taking 200 mg qd had a reaction.[94] Lichenoid reactions accounted for approximately 20 percent of the reactions in this series. CQ has an affinity for melanin and is thus concentrated in the skin. The binding of drug molecules to melanin may cause a blue-black discoloration of the skin in 10 percent to 25 percent of patients treated with these compounds for a prolonged course. Shins, face, hard palate, and nail beds are commonly affected.[99,100] The discoloration may fade slowly over months after the drug is discontinued. QE also binds melanin and may cause hyperpigmentation similar to that seen with CQ. More commonly, a dose-related yellowish staining occurs and affects the skin, sclera, and bodily secretion. This also tends to fade over time after drug withdrawal. Stevens-Johnson syndrome has been reported in a patient treated with HCQ.[101]

Ocular toxicity is the most worrisome side effect of antimalarial therapy. Neuromuscular eye toxicity, corneal deposits, and potentially irreversible retinopathy can all occur. Blurred vision and reduction in accommodation power can occur from the depressive effect on ocular muscles during the initial weeks of therapy (transient and self-limited). CQ is deposited in the basal epithelium of the cornea. Deposition of HCQ can also occur but is less likely at therapeutic doses.[102] These depositions can be responsible for patient complaints of blurred vision, halos around lights, and photophobia.[103] The corneal deposits are dose related, reversible with cessation of

TABLE 227-3
Risks and Precautions

- Possible side effects from antimalarial compounds
  - Gastrointestinal: Anorexia, nausea, vomiting, diarrhea, weight loss, hepatotoxicity
  - Hematologic: Hemolytic anemia (glucose-6-phosphate dehydrogenase deficiency), aplastic anemia, agranulocytosis, pancytopenia
  - Mucocutaneous: Pigmentation—blue gray, yellow (quinacrine), rashes (urticaria, morbilliform, lichenoid, exfoliative dermatitis, acute generalized exanthematous pustulosis), pruritus, worsening psoriasis
  - Ophthalmologic: Neuromuscular eye toxicity (diplopia, blurred vision, loss of accommodation), corneal deposits (halos around lights, photophobia), retinopathy (pre-maculopathy—reversible and true retinopathy—irreversible; not seen with quinacrine therapy)
  - Neuromuscular: Nightmares, vertigo, tinnitus, nervousness, irritability, toxic psychosis, seizures, neuromyotoxicity, myasthenia-like syndrome, ototoxicity, rhabdomyolysis
  - High doses: Cardiovascular toxicities, hypotension, neurotoxicity, respiratory or cardiac arrest, death
- Drug interactions
  - Penicillamine and digoxin levels may be increased with concurrent use of CQ or HCQ
  - Cyclosporin levels may be increased with use of CQ
  - Metoprolol levels may be increased with use of HCQ
  - Ampicillin bioavailability may be decreased when used with CQ
  - Antacids and Kaolin may decrease gastrointestinal absorption of CQ
  - Cimetidine may increase CQ levels
  - Mefloquine used with CQ may increase risk of seizures
  - Smoking decreases efficacy of antimalarial drugs by inducing the cytochrome P_{450} system
- Special precautions
  - Dosing in children must consider weight to decrease risk of toxicity
  - Use in pregnancy is relatively contraindicated (congenital defects are rare)
  - Use in breast-feeding is relatively contraindicated (CQ and HCQ are excreted in breast milk)

CQ = chloroquine; HCQ = hydroxychloroquine.



therapy, and not a contraindication for continued therapy. CQ has an affinity for retinal pigment epithelium and can be stored there for years, even after discontinuation of therapy. Antimalarial-induced retinopathy can be reversible (pre-maculopathy) or irreversible (true retinopathy). Pre-maculopathy includes changes in visual fields or funduscopic examination not associated with vision loss. These changes may progress to irreversible disease if the offending drug is not discontinued. True retinopathy is associated with bilateral, permanent visual field abnormalities. Risk of true retinopathy from antimalarial therapy has been studied and debated. It appears as though the risk is greater for CQ than HCQ.[102,104] Doses less than 4.0 mg/kg/day for CQ and less than 6.5 mg/kg/day for HCQ are believed to decrease the risk of a true retinopathy.[105] Higher doses and impaired renal function may increase the risk. The true risk of HCQ-induced retinopathy is felt to be quite rare. As such, the question of screening as a cost-effective measure is debated. A case of bull's eye maculopathy has been associated with QE therapy for malaria.[106]

Other, less likely side effects of antimalarial therapy include neuromyotoxicity,[107] ototoxicity,[108,109] acute generalized exanthematous pustulosis,[110] and rhabdomyolysis.[111]

Drug Interactions

Few drug interactions have been reported with concurrent use with antimalarial drugs. Penicillamine or digoxin levels may be increased when used with CQ or HCQ.[48,49] Cyclosporin levels may be increased by CQ.[48] Metoprolol levels may be increased with use of HCQ.[112] CQ may reduce the bioavailability of ampicillin.[48] Antacids and Kaolin may decrease the GI absorption of CQ. A minimum of 4 hours should exist between administration of antacids and antimalarials.[48] Cimetidine may increase CQ levels,[48] increasing potential for other side effects. Concurrent use CQ and mefloquine may increase the risk of seizures. CQ increases the risk of hepatotoxicity when administered with other hepatotoxic agents. Monitoring liver enzymes is recommended.[48] Finally, smoking induces the cytochrome P_{450} enzyme system and may alter the bioavailability of antimalarial therapy. Decreased efficacy of antimalarial therapy in smokers has been published.[113]

Pediatric Use

CQ and HCQ have been used in the pediatric population.[114,115] However, concern over toxicity exists.[116,117] Milligram-per-kilogram, antimalarials are now considered generally safe in children when treating connective tissue diseases, juvenile rheumatoid arthritis, morphea, panniculitis, or PCT.[118] Risk for toxicity in children is felt to be no greater than for adults when accounting for body weight.

Pregnancy

Use of antimalarial drugs in pregnancy is controversial but now generally accepted as safe. It is recognized that 4-aminoquinalines cross the placenta and accumulate in fetal tissues.[52] Congenital defects have been rarely reported with antimalarial drug use in pregnancy.[119] In one study of 27 pregnancies exposed to HCQ or CQ, no congenital anomalies were identified.[120] Another review of 33 lupus patients with 36 pregnancies exposed to HCQ reported no evidence of teratogenic effects.[121] Larger reviews in Britain and North America support the use of 4-aminoquinalines during pregnancy.[122–124] In addition, discontinuation of antimalarial therapy for the treatment of lupus may cause a significant flare-up of disease, which can be associated with prematurity, growth retardation, and increased fetal loss.[125–128] Safety of QE is less well documented.

Breast-Feeding

Antimalarial use during breast-feeding is relatively contraindicated. CQ and HCQ are both excreted in breast milk.[129] In the case of HCQ, infants are exposed to 2 percent of the maternal dose per kilogram per day and 1 percent of the maternal dose of CQ.[57] As the half-life is long and elimination slow, potential exists for accumulation of drug in the infant.[130]

CHAPTER 228

Cytotoxic and Antimetabolic Agents

Whitney A. High
James E. Fitzpatrick

Cytotoxic and antimetabolic agents may be used to treat severe or refractory skin disease. The toxicities of such agents are significant and must be balanced against therapeutic advantage. In treating skin disease, most of these agents are utilized at immunomodulatory rather than cytotoxic dosages.

Cytotoxic and antimetabolic drugs modulate the behavior of inflammatory and other cells through inhibition of cell growth and development. The cell cycle represents a conceptual schema for the sequence of growth experienced by essentially all cells (see eFig. 44-2.1 in online edition). The cycle begins with the G_1 phase, which is directed toward preparing the cellular apparatus for DNA synthesis. The S phase follows G_1 and is devoted to DNA synthesis. At the end of DNA synthesis, the G_2 phase occurs. The G_2 phase is followed by the M phase, or actual cell division. Some cells may also enter a resting state of indeterminate length, termed G_0. Specific cytotoxic drugs may be effective at different stages of the cell cycle.

The cytotoxic drugs commonly used in dermatology fall into two classes: antimetabolites and alkylating agents. Antimetabolites mimic natural molecules and are most active while DNA is being synthesized (S phase). Alkylating agents exert effect through physicochemical interactions with DNA, such as alkylation, cross-linking, and carbamylation. The effects of alkylating agents are generally independent of the cell cycle.

The immunosuppressive properties of cytotoxic agents provide benefit in immunologically mediated disease, yet these agents may predispose to infection as well. Potentially lethal infections may arise quickly in an immunosuppressed patient. Those placed on cytotoxic agents should be queried at each visit for symptoms of infection, such as fever, chills, sweating, shortness of breath, cough, headache, dysuria, and arthritis. Prompt reporting of symptoms should be encouraged.

ANTIMETABOLIC AGENTS

Methotrexate

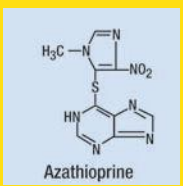
Methotrexate remains one of the most frequently employed antimetabolic agents in dermatology. With appropriate monitoring, an impressive record of safety has accumulated for methotrexate. Concerns regarding use of methotrexate are best addressed through increased drug awareness, rational patient selection, appropriate laboratory monitoring, and, most recently, folate supplementation.

MECHANISM OF ACTION Methotrexate is an analog of folate that competitively and irreversibly inhibits dihydrofolate reductase (Fig. 228-1). Methotrexate also partially inhibits thymidylate synthetase. Through inhibition of these enzymes, methotrexate decreases the availability of reduced folate and thymidylate necessary for RNA and DNA synthesis. Other inhibitors of folate metabolism, such as trimethoprim-sulfamethoxazole, may potentiate the toxicity of methotrexate (see Drug Interactions).

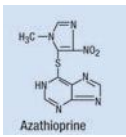
Like folate itself, the activity of methotrexate is enhanced by glutamylation. Glutamylation also yields additional anti-inflammatory properties.[1] First, by inhibiting aminoimidazole carboxamide ribonucleoside transformylase, methotrexate-polyglutamate increases the local tissue concentration of adenosine, which has potent anti-inflammatory action. Second, by decreasing available tetrahydrofolate, methotrexate decreases the production of S-adenyl methionine, which also results in decreased inflammation.

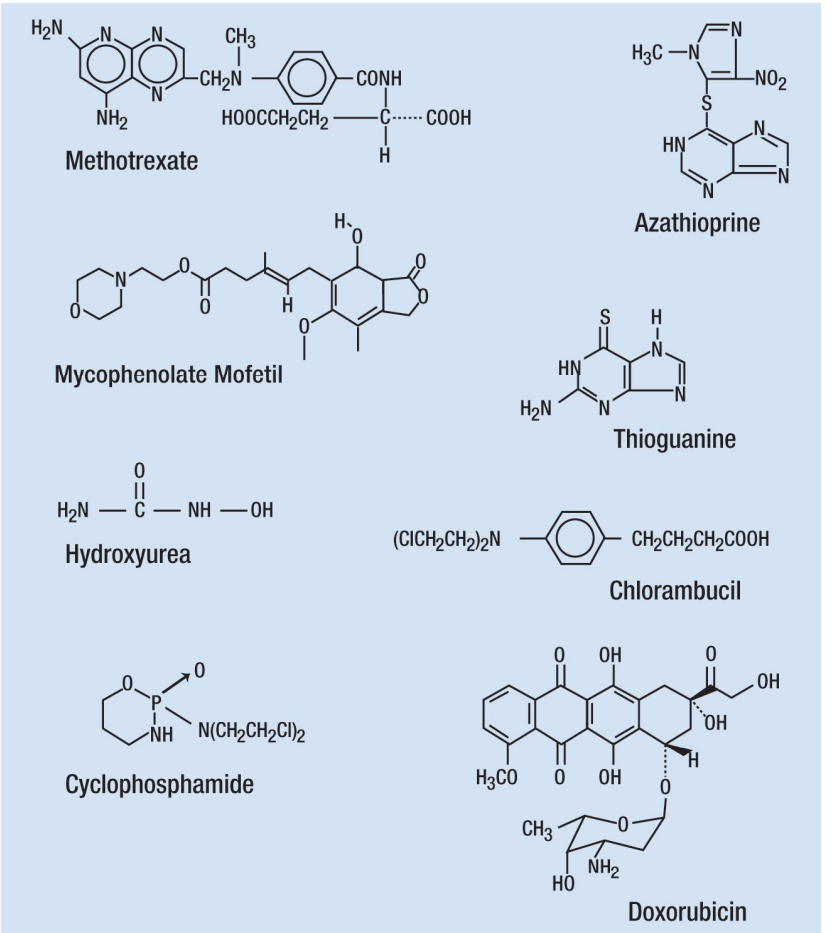
PHARMACOKINETICS Oral methotrexate is absorbed rapidly through the gastrointestinal tract. In children, absorption is decreased by concurrent ingestion of food and milk, but this has not been observed in adults. In adults, the mean bioavailability is 67 percent of the administered dose. Peak plasma levels

CYTOTOXIC AND ANTIMETABOLIC AGENTS AT A GLANCE



- Cytotoxic and antimetabolic agents are used in dermatology to treat serious, life-threatening, and recalcitrant disease.
- Common agents used in dermatology include methotrexate, azathioprine, mycophenolate mofetil, thioguanine, hydroxyurea, cyclophosphamide, chlorambucil, and liposomal doxorubicin.
- Methotrexate is U.S. Food and Drug Administration (FDA) approved for treatment of psoriasis and advanced mycosis fungoides, whereas cyclophosphamide is FDA approved for advanced mycosis fungoides only, and liposomal doxorubicin is approved for acquired immunodeficiency symdrome–related Kaposi sarcoma; other uses of the agent in this chapter occur on an "off-label" basis.
- Cytotoxic and antimetabolic agents act through inhibition and/or interruption of the cell cycle.
- Side effects and complications with these potentially dangerous medications are numerous, and close clinical follow-up and laboratory evaluation is necessary.
- Cytotoxic agents used in dermatology, as well as those initiated for other purposes, may yield distinctive cutaneous eruptions and cutaneous sequelae.





▲ **FIGURE 228-1** Chemical structure of cytotoxic agents most often used in dermatology.

occur 1 to 3 hours after administration. The half-life of the drug is 4 to 5 hours. For doses higher than 25 mg/week, gastrointestinal absorption is more erratic, and some experts recommend intramuscular dosing above this level.[2]

Methotrexate is eliminated chiefly by the kidneys, with 60 percent to 95 percent excreted unchanged. Decreases in glomerular filtration or tubular secretion may lead to methotrexate toxicity. Approximately 50 percent of methotrexate within the blood is protein bound. Weak organic acids, such as aspirin or other nonsteroidal anti-inflammatory agents, may displace methotrexate, altering blood levels and renal excretion (see Drug Interactions).

INDICATIONS Methotrexate is used for many purposes in dermatology, but its chief indication is for treatment of severe psoriasis. The anti-psoriatic effects of methotrexate were first recognized in the late 1950s and 1960s,[3] and by the late 1980s, more than one-half of dermatologists reported using methotrexate to treat severe psoriasis.[4] The impact of an increasing number of systemic treatments for psoriasis (the "biologics"; see Chap. 235) has not been fully studied, but certainly these agents may decrease methotrexate use. Methotrexate has also been used in a variety of other autoimmune and connective tissue diseases, vasculitides, inflammatory dermatoses, and papulosquamous conditions (Table 228-1).

DOSING REGIMEN Typical oncologic doses of methotrexate (100 to 250 mg/m^2/week) are cytotoxic; however, lower doses (7.5 to 25.0 mg/week) are immunomodulatory. In dermatology, methotrexate doses are typically less than 30 mg/week, and are often less than 17.5 mg/week. Cumulative dose must be tracked and recorded, as this impacts monitoring during continued use (see Monitoring Therapy).

Methotrexate is available in 2.5-mg tablets. For those with economic limitations, methotrexate liquid (25 mg/mL) may be more affordable for peroral use.[5] Either a single weekly dose or a weekly dose divided into three portions separated by 12 hours is used. These dosing regimens have essentially equal efficacy, although the split dose may increase tolerance by minimizing gastrointestinal upset.

INITIATING THERAPY Evaluation before methotrexate use includes a careful history and physical examination, and assessment of concomitant conditions or medications that limit methotrexate use. Exclusion of patients inappropriate for methotrexate therapy is an important first step in management. Methotrexate is relatively contraindicated in those with hepatic disease (including viral hepatitis), significant renal disease, active infection, or those with excessive alcohol consumption. In general, the elderly are often less amenable to methotrexate therapy due to declining renal function. Administration of methotrexate to pregnant women or nursing mothers is strictly contraindicated. Consensus is lacking with regard to the use of methotrexate in human immunodeficiency virus-positive (HIV+) individuals, but caution is advised.[6] Baseline laboratory studies include a complete blood cell count (CBC) with manual differential and platelet count; liver function testing; serologic assessment for hepatitis A, B, and C antibodies; renal function assessment; and HIV screening if indicated.[7]

Initiation of methotrexate therapy involves a test dose. Patients selected appropriately on the basis of disease severity, general health, personal habits, and satisfactory baseline laboratory values are given a single 5- to 10-mg test dose. Repeat laboratory studies, a skin examination, and a review of systems are conducted 1 week later. Performance of repeat laboratory studies sooner than 5 to 6 days after dosing yields only expected elevated liver transaminases and may confound interpretation.

If all data are acceptable, weekly therapy may commence using a dose of ap-

Uses for Methotrexate in Dermatology

- U.S. Food and Drug Administration–approved indications
  - Severe psoriasis (± psoriatic arthritis)
  - Mycosis fungoides (advanced disease)
- "Off-label" uses
  - Dermatomyositis
  - Cutaneous lupus erythematosus
  - Scleroderma
  - Pemphigus vulgaris
  - Bullous pemphigoid
  - Cutaneous polyarteritis nodosa
  - Behçet disease
  - Pyoderma gangrenosum
  - Lymphomatoid papulosis
  - Pityriasis lichenoides et varioliformis acuta
  - Pityriasis rubra pilaris
  - Sarcoidosis
  - Severe atopic dermatitis
  - Chronic hand dermatitis

TABLE 228-2
Safety Monitoring for Methotrexate Use

Initial Evaluation	Ongoing Laboratory Monitoring

• Careful history and physical examination
• Identification of proper patient characteristics and risk factors
• Survey for interacting medications (aspirin, nonsteroidal anti-inflammatory drugs, trimethoprim-sulfamethoxazole, etc.)
• Baseline laboratories:
  • CBC with differential/platelets
  • Liver function tests
  • Serology for hepatitis A/B/C
  • Renal function testing (creatinine/blood urea nitrogen)
  • Human immunodeficiency virus screening (if applicable)
	• CBC with differential/platelets and liver function tests
	  • Perform weekly for 2–4 wk
	  • Gradually increase to every 3–4 mo with time
	  • Perform 5–6 days after any dose escalation
	• Renal function tests
	  • Perform once or twice yearly or if suspicion of change in renal function arises
	• Liver biopsy
	  • Perform after 1.5 g (cumulative dose) if no risk factors, then every 1 g thereafter
	  • Perform early in therapy if risk factors exist

CBC = complete blood cell count.

proximately 10 mg/week, depending on the severity of disease, overall health, and ideal body weight of the patient. The dose may be increased by 2.5 to 5.0 mg every 2 to 4 weeks until adequate control is achieved or toxicity ensues. When improvement has stabilized, the dose may be tapered in 2.5-mg decrements to a point at which disease activity increases slightly. The goal is to allow mild or low-grade psoriasis activity to avoid an unacceptably high dose. It is important to discuss this expectation with the patient to prevent confusion regarding the endpoint. Concomitant topical therapy may minimize the methotrexate dose needed for satisfactory control.

If a patient does not demonstrate satisfactory improvement on a dose of 20 to 25 mg/week, consideration of alternative agents is indicated. Occasional patients with refractory disease may respond better to parenteral methotrexate, typically intramuscular dosing. In refractory cases, methotrexate may be combined with ultraviolet B (UVB) phototherapy, psoralen and UVA light, or oral retinoids to enhance efficacy.[7]

MONITORING THERAPY Ongoing laboratory evaluation during methotrexate therapy should include a CBC with manual differential and platelet count and liver function tests weekly for 2 to 4 weeks, then increasing gradually to every 3 to 4 months. Always repeat testing with any dose escalation or intercurrent illness. Liver function testing should not be performed earlier than 5 days after dosing to avoid confounding results. Renal function tests should be performed once or twice yearly, or with any suspicion of altered renal function.

A consensus conference of dermatologists has recommended liver biopsy be performed in those without risk factors after administration of the first 1.0 to 1.5 g of methotrexate and at or near the beginning of treatment in those with risk factors for liver disease.[7] If methotrexate is continued, a repeat biopsy should occur at 3 g, and every 1.0 to 1.5 g thereafter. In those patients with an indication for an early biopsy (e.g., obesity, diabetes, history of liver disease), consideration of a short delay of 2 to 4 months after initiation of therapy may prevent an unnecessary liver biopsy in those patients who will not continue therapy. Safety guidelines used during methotrexate therapy are summarized in Table 228-2.

RISKS AND PRECAUTIONS Absolute and relative contraindications and common adverse effects of methotrexate are summarized in Table 228-3.

COMPLICATIONS Adverse reactions to methotrexate range from the trivial to life-threatening.

Gastrointestinal Effects. Nausea and vomiting with oral administration is common and dose related. Such effects may be seen with parenteral dosing as well. Indeed, 10 percent to 30 percent of all patients placed on methotrexate may experience some gastrointestinal upset. Symptoms may even occur before dosing or 24 to 36 hours afterward, suggesting a psychosomatic or anticipatory basis in select cases. Supplementation with folate (1 to 5 mg/day) reduces gastrointestinal symptoms without compromising efficacy.[8–11]

TABLE 228-3
Risks and Precautions with Methotrexate Use

- Absolute contraindications
  - Pregnancy (Category X)
  - Lactation
- Relative contraindications
  - Renal dysfunction (dose may be reduced)
  - Hematologic disease (dose may be reduced)
  - Hepatic disease or hepatic dysfunction
  - Unreliable patient
  - Excessive alcohol consumption
  - Diabetes mellitus and/or obesity
  - Active infection and/or potential reactivation of infection (tuberculosis)
  - Human immunodeficiency virus infection (controversial)
  - Man or woman contemplating impending conception
- Common adverse effects
  - Gastrointestinal distress (minimized with folate supplementation)
  - Myelosuppression (acute)
  - Toxic hepatitis
  - Liver fibrosis/cirrhosis (chronic)

Hepatic Effects. Induction of liver fibrosis is a major concern with methotrexate use. Methotrexate is hepatotoxic, and some elevation in liver transaminases is expected. These elevations occur near to administration and are not strictly predictive of those predisposed to fibrosis. Fibrosis in the absence of elevated transaminases is well described.[12,13] Dose reduction or discontinuance is indicated if transaminases exceed twice normal values when measured 5 to 6 days after the last dose. For reasons that are unclear, psoriasis patients appear to have a higher incidence of liver fibrosis than do rheumatoid arthritis patients despite similar treatment doses. The confounding effect of alcohol among psoriasis patients has been asserted as a possible explanation.[14]

Hepatic fibrosis relates to duration of therapy, cumulative dose, patient age, and comorbid conditions. The data on methotrexate-induced liver fibrosis vary widely, with a reported prevalence of 0 percent to 25 percent. The risk of liver disease appears low in those with a cumulative dose less than 1.5 g.[7] Patients with prior liver disease, diabetes, obesity, significant alcohol intake, and intravenous drug use are at increased risk for hepatic fibrosis.

The gold standard for assessing methotrexate-induced liver fibrosis is percutaneous needle biopsy. The procedure is not without risk; minor bleeding occurs in 1 in 1000 patients, and the risk of death is

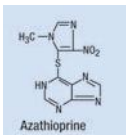

TABLE 228-4
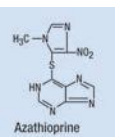
Classification of Liver Biopsy Findings for Methotrexate Use

Biopsy Grade	Histopathologic Findings	Recommended Action
I	Normal; fatty infiltration (mild), portal inflammation (mild)	Continue methotrexate
II	Fatty infiltration (moderate to severe), portal inflammation (moderate/severe)	Continue methotrexate
IIIA	Fibrosis (mild)	Continue methotrexate; repeat biopsy in 6 mo
IIIB	Fibrosis (moderate to severe)	Discontinue methotrexate
IV	Frank cirrhosis	Discontinue methotrexate



Azathioprine

estimated at 1 in 10,000.[15] Specimens are assessed for lobular architecture, inflammation and fibrosis, and fat infiltration. A grading scheme using a scale of I to IV is widely used (Table 228-4). Patients with grades I and II histology may continue methotrexate, those with grade IIIA histology may continue with a repeat liver biopsy in 6 months, and those with grades IIIB and IV histology should discontinue methotrexate.[7]

A non-invasive test for liver fibrosis would be ideal. Ultrasound alone has demonstrated conflicting results.[16,17] Radionuclide scans and the aminopyrine breath test have proven inadequate for independent detection of methotrexate-induced fibrosis.[18,19] Serum assay of the amino terminus of type III procollagen peptide (PIIINP) may suggest fibrosis; however, specificity is limited. PIIINP is simply a marker of fibrogenesis, and it may be elevated during fibrosis of any organ system.[20] It is unreliable in patients with psoriatic arthritis. A compelling argument has been made to use an amalgam of tests, such as ultrasound, dynamic radionuclide scanning, and PIIINP assay, to reduce the number of required liver biopsies. Nevertheless, at present, percutaneous liver biopsy remains the standard of care.[14,21]

Hematologic Effects. The most important acute adverse effect of methotrexate is myelosuppression. Anemia, neutropenia, and thrombocytopenia may result from methotrexate use. Risk factors for bone marrow toxicity include advanced age, poor renal function, and concurrent administration of conflicting medications (see Drug Interactions).

Mucosal and Cutaneous Effects. Oral ulcerations or stomatitis may be noted with methotrexate use. Skin ulceration, particularly of the lower legs, may herald bone marrow suppression. In patients treated with methotrexate for psoriasis, rapid ulceration of psoriatic plaques may also suggest toxicity.[22] Laboratory studies and dose reduction or complete discontinuance is indicated when mucocutaneous ulcerations or skin ulcerations develop, respectively. Methotrexate may also engender a cutaneous "recall reaction" in areas of prior irradiation or recent sunburn.[23] Mild alopecia has been described with methotrexate use. Other cutaneous manifestations include acral erythema, epidermal necrosis, and vasculitis.

Carcinogenecity. Low-dose methotrexate use has not been definitively associated with carcinogenesis. In a study that demonstrated a slight increase in lymphoma among psoriatic patients within the United Kingdom, use of methotrexate was not discriminatory.[24]

Mutagenecity and Teratogenecity. Methotrexate is a Category X agent during pregnancy, and administration is absolutely contraindicated (see Table 228-3). Pregnancies that occur after the discontinuation of methotrexate appear unaffected, but it is generally advocated that men wait 3 months after discontinuance before attempting conception; women should wait one complete menstrual cycle. Reliable contraception is requisite while taking methotrexate.[7]

Pulmonary Effects. Acute pneumonitis and pulmonary fibrosis have been reported with methotrexate use in psoriasis, although such reactions are more common in rheumatoid arthritis patients.[25] Pulmonary toxicity likely represents an idiosyncratic reaction. Chest radiographs and pulmonary function testing are not useful in the detection or prevention of pulmonary fibrosis.[26] A chest x-ray should be performed in those with symptoms of pneumonitis. Discontinuance is recommended if examination findings are concerning.

Opportunistic Infections. Opportunistic infections (e.g., *Pneumocystis* pneumonia, cryptococcosis, and histoplasmosis) have been reported in otherwise healthy individuals receiving low-dose methotrexate.[27–30] Admittedly, such patients were often using other immunosuppressive medications as well; often prednisone.

Anaphylaxis. Systemic anaphylaxis with low-dose methotrexate has been reported.[31] Many patients had received methotrexate before at comparable doses without untoward effects.

Folate and Folinic Acid Supplementation. Daily supplementation with 1 to 5 mg of folate has reduced nausea, vomiting, stomatitis and oral ulceration, elevated transaminases, and mild myelosuppression without compromising the efficacy of methotrexate.[8–11] Liver fibrosis, pneumonitis, and moderate to severe myelosuppression are not mitigated by folate supplementation. Elevated homocysteine levels, common with methotrexate use and an independent risk factor for coronary artery disease, are decreased with folate supplementation.[32]

Folinic acid should not be given on the same days as methotrexate dosing. Unlike folinic acid, folate does not compete with methotrexate for cellular uptake. Folate is also considerably cheaper than folinic acid. For these reasons, folate supplementation is preferred by many authorities. One drawback to folate supplementation is the potential masking of vitamin B_{12} deficiency. Use of folate supplementation with methotrexate therapy is increasing rapidly.

Overdose. Methotrexate overdose is more likely in patients with declining renal function, in those who misunderstand dosing directions, or in those concomitantly exposed to a second folate antagonist, such as trimethoprim-sulfamethoxazole. Overdose should be treated promptly with folinic acid (leucovorin). Folinic acid is metabolized in vivo to tetrahydrofolate in the absence of dihydrofolate reductase, providing an alternative supply of DNA and RNA precursors.

Folinic acid should be given early, preferably within the first 24 to 36 hours after overdose. Folinic acid itself has very little toxicity. Therefore, an oral dose of 10 mg/m^2 should be given on first suspicion of methotrexate overdose without delay for a serum assay. Peroral or parenteral doses may be continued every 6 hours until the serum concentration of methotrexate falls to less than 10^{-8} M.[7] Practically speaking, or when a serum assay is unavailable, this recommendation is often equiva-

lent to 15 to 25 mg of folinic acid by mouth every 6 hours for 6 to 10 doses.

Drug Interactions. Although any drug that may enhance methotrexate toxicity should be avoided during therapy, there are several near-absolute contraindications, including aspirin, other nonsteroidal anti-inflammatories, probenecid, and trimethoprim-sulfamethoxazole.[33]

Azathioprine

Azathioprine is a synthetic analog of natural purine bases used in RNA and DNA synthesis (see Fig. 228-1). Although many thiopurine derivatives exist, azathioprine is the agent most often used in dermatology.

MECHANISM OF ACTION Azathioprine is a prodrug that is metabolized in the body to 6-mercaptopurine (6-MP). 6-MP is further anabolized via hypoxanthine-guanine phosphoribosyl transferase (HGPRT) to a purine analog that inhibits RNA and DNA synthesis and repair, yielding immunosuppression. HGPRT activation is critical. Patients with Lesch-Nyhan syndrome (HGPRT deficiency) experience no immunosuppression or untoward effects while taking azathioprine.[34]

PHARMACOKINETICS Azathioprine and its metabolite, 6-MP, are equally potent when administered parenterally, but azathioprine enjoys improved bioavailability, with 88 percent of the oral dose being absorbed through the gastrointestinal tract. After absorption, azathioprine is converted to 6-MP, mostly within erythrocytes. The fate of 6-MP is determined by one of three competing metabolic pathways: (1) it may be anabolized to an active form via HGPRT, (2) it may be catabolized to an inactive form via xanthine oxidase (XO), or (3) it may be catabolized to an inactive form by thiopurine methyltransferase (TPMT).[35]

Elucidation of the TPMT-dependent catabolic pathway has revolutionized the clinical use of azathioprine. In humans, expression of TPMT is variable due to genetic polymorphisms. Patients may be categorized into three subgroups: (1) a large majority possesses high levels of TPMT expression (89 percent), (2) intermediate expression is demonstrated in 11 percent, and (3) less than 1 percent demonstrate low TPMT activity (1 in 300 persons).[36] Commercial assays for TPMT activity allow for graduated azathioprine dosing, with improved efficacy and a lesser incidence of unforeseen side effects (see Dosing Regimen).[37,38]

XO is another enzyme involved in the catabolism of 6-MP. Allopurinol, used in the treatment of gout, is a potent inhibitor of XO; toxicity may result in those taking both medications.[39] Unlike TPMT, there is very little genetic variation in XO expression, and it is unnecessary to assess innate XO expression before azathioprine dosing. A careful medication history, however, is critical (see Drug Interactions).

INDICATIONS In dermatology, azathioprine is used "off-label" chiefly as a steroid-sparing agent for immunobullous disorders, including pemphigus, cicatricial pemphigoid, and severe or recalcitrant bullous pemphigoid (Table 228-5).[40] In a prospective, long-term study of pemphigus vulgaris patients treated with glucocorticoids and azathioprine, 45 percent achieved remission.[41] The steroid-sparing effect of azathioprine in pemphigus has been challenged in literary review, but not in a clinical trial; it remains a common regimen among practicing dermatologists.[42]

DOSING REGIMEN Azathioprine is supplied as 50-mg tablets and also as an injectable. Traditionally, a dose of 1 to 2 mg/kg/day of azathioprine was used, often concurrent with high-dose prednisone. Increasingly, the appropriate dosage is now based on a patient's own TPMT expression (Table 228-6).[37] Impaired renal function may be associated with greater toxicity, and the dosage may still be adjusted for this reason.

TABLE 228-5
Uses for Azathioprine in Dermatology

- U.S. Food and Drug Administration–approved indications
  - None
- "Off-label" uses
  - Dermatomyositis
  - Severe cutaneous lupus erythematosus
  - Scleroderma
  - Relapsing polychondritis
  - Pemphigus vulgaris
  - Bullous pemphigoid
  - Cicatricial pemphigoid
  - Cutaneous polyarteritis nodosa
  - Severe or recalcitrant leukocytoclastic vasculitis
  - Behçet disease
  - Pyoderma gangrenosum
  - Sarcoidosis
  - Severe psoriasis
  - Severe lichen planus
  - Severe atopic dermatitis
  - Chronic actinic dermatitis
  - Severe contact dermatitis
  - Severe polymorphous light eruption

TABLE 228-6
Dosing of Azathioprine Based on Thiopurine Methyltransferase (TPMT) Enzyme Assay

TPMT Erythrocyte Assay	Maximum Azathioprine Dose
> 19.0 U (high expression)	2.5 mg/kg/day
13.7–19.0 U (intermediate expression)	1.5 mg/kg/day
5.0–13.7 U (low expression)	0.5 mg/kg/day

INITIATING THERAPY Before therapy, the patient should receive a complete history and physical examination. Exclusion of patients with severe co-morbidities, active infections, or the possibility of reactivation of an infection (tuberculosis) is recommended. All women of childbearing age should receive a pregnancy test. Patients with a history of exposure to alkylating agents should likely not receive azathioprine unless unavoidable, as an increased risk of lymphoproliferative disease exists when used in succession.

Baseline laboratory tests include a CBC with manual differential and platelet count, renal and liver function testing, and an erythrocyte TPMT activity assay should be performed. There are reports of mycobacterial infection in those taking azathioprine, and tuberculin screening should be considered. In steroid-responsive bullous disorders and in connective tissue disease, experienced practitioners often initiate azathioprine concurrently with high-dose steroids.

MONITORING THERAPY During therapy, a CBC with manual differentiation and platelet count and liver function testing should be obtained biweekly to monthly for the first 2 to 3 months, and every 2 months thereafter. Additional laboratory testing is necessary with dosage increases or if an initial TPMT level cannot be determined. Biannual physical examinations should pay particular attention to evidence of possible lymphoreticular disease and skin cancer, particularly squamous cell carcinoma (SCC). Safety guidelines used during azathioprine therapy are summarized in Table 228-7.

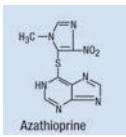


TABLE 228-7
Safety Monitoring for Azathioprine Use

- Initial evaluation
  - Careful history and physical examination
  - Identification of proper patient characteristics and risk factors
  - Survey for interacting medications (allopurinol, aminosalicylates)
  - Baseline laboratories:
    - Thiopurine methyltransferase erythrocyte assay
    - CBC with differential/platelets
    - Basic serum chemistry profile
    - Liver function tests
    - Urinalysis
    - Pregnancy testing for women of childbearing age
    - Tuberculin testing (if indicated)
- Ongoing laboratory monitoring
  - CBC with differential/platelets and liver function tests
    - Perform monthly for 3 mo, then
      - ~ Increase to bimonthly
      - ~ Perform 5–6 days after any dose escalation
- Follow-up clinical evaluation
  - Biannual complete physical examinations
    - Particular attention to possible lymphoreticular disease (adenopathy)
    - Careful survey for non-melanoma skin cancer (squamous cell carcinoma)

CBC = complete blood cell count.

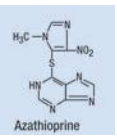

TABLE 228-8
Risks and Precautions with Azathioprine Use

- Absolute contraindications
  - Hypersensitivity to azathioprine
  - Active or ongoing infection
- Relative contraindications
  - Pregnancy/lactation (Category D, but myelosuppression of fetus/infant common—avoid)
  - Allopurinol use (dose must be reduced by 75%)
  - Prior lymphoproliferative disease or prior use of alkylating agents
- Common adverse effects
  - Gastrointestinal distress (minimized by administration with food)
  - Myelosuppression
  - Possible increased risk of lymphoproliferative disease or skin cancer
  - Possible opportunistic infections

RISK FACTORS AND PRECAUTIONS Absolute and relative contraindications and common adverse effects of azathioprine are summarized in Table 228-8.

COMPLICATIONS With careful monitoring, azathioprine is generally safe. A comparison of rheumatoid arthritis patients treated with methotrexate or azathioprine failed to reveal significant differences in adverse effects.[43] Adverse effects tend to occur in those patients with lower TPMT activity levels, higher doses of azathioprine, or concomitant use of allopurinol.

Hematologic Effects. Myelosuppression is a major side effect of azathioprine use. Generalized depression of all blood cell lines is most common, but depression of any single lineage may be observed. Thrombocytopenia is a common initial presentation of bone marrow toxicity. Bone marrow suppression tends to occur at higher doses and in those with lower TPMT expression.[44] Discontinuance usually results in complete marrow recovery.

Opportunistic Infections. Most patients treated with azathioprine also receive large doses of glucocorticoids. Therefore, it is often difficult to quantify the independent role of azathioprine in any predisposition toward infection. Herpes virus infections, human papilloma infection, and scabies infestation have been reported in those taking azathioprine.[45]

Gastrointestinal Effects. Patients receiving high doses of azathioprine may experience nausea, vomiting, and diarrhea. Such symptoms are not usually treatment limiting and may be reduced by administration with food.

Hepatic Effects. Toxic hepatitis has developed in approximately 1 percent of patients treated with azathioprine for rheumatoid arthritis, and it is usually reversible.[45] Other adverse effects include hepatic venoocclusive disease and associated pancreatitis. Discontinuance is warranted with evidence of liver toxicity.

Anaphylaxis. Azathioprine-induced shock and hypersensitivity reactions have been reported in patients with cutaneous disease. In most cases, hypotensive collapse occurred within hours of the initial dose. Drug fever has also been reported with azathioprine (see Chap. 40).

Carcinogenesis. An increased risk of lymphoproliferative disease has been documented in renal transplant recipients, rheumatoid arthritis patients, and, most recently, inflammatory bowel disease patients treated with chronic azathioprine.[46–48] In one study, the relative risk was increased roughly 10- to 13-fold, or one lymphoma per 1000 patient-years of azathioprine treatment. Dermatologic doses of azathioprine are often lower and the duration of treatment shorter, leading to speculation that the risk of lymphoma is probably lower in those treated for cutaneous disease. However, the most recent meta-analysis of patients treated with azathioprine for inflammatory bowel disease who developed lymphoma included those on "low-dose" regimens.[48] In light of this information, it seems prudent to inform patients that the exact magnitude of any increased risk for lymphoma with "low-dose" azathioprine is largely unknown. Patients with a prior exposure to alkylating agents may have a prohibitive risk of lymphoma if treated subsequently with azathioprine; great caution is suggested in this population.

Aggressive behavior of SCC has been described in patients taking azathioprine for eczema, atopic dermatitis, and chronic actinic dermatitis.[49] It was recently suggested that azathioprine used in solid organ transplant recipients may sensitize DNA to UVA radiation, leading to the increased incidence of SCC in this population.[50] Admittedly, confounding risk factors exist. Dermatologists should be aware of this emerging research, as only broad spectrum sunscreens mitigate UVA exposure, and such rays are not blocked by glass.

Mutagenecity and Teratogenecity. Azathioprine is a Category D agent during pregnancy. The prodrug and the active metabolites readily cross the placenta. The rate of congenital malformation appears to be low (4.3 percent), but myelosuppression and immunosuppression are significant occurrences in neonates and breast-fed infants. Fertility of men or women appears unaffected by azathioprine.[51]

Drug Interactions. A major drug interaction occurs between azathioprine and allopurinol. When allopurinol must be used concurrently, the azathioprine dose must be decreased by 75 percent. There is evidence that aminosalicylates may inhibit TPMT activity, and it may be prudent to minimize or avoid such medications in patients using azathioprine.

Mycophenolic Acid and Mycophenolate Mofetil

Mycophenolic acid (MPA) (see Fig. 228-1) is a lipid-soluble, weak organic acid with antifungal, antibacterial, antiviral, and immunosuppressive properties. MPA was first used as an oral agent for moderate to

severe psoriasis in the 1970s, but use was discontinued due to intolerability. Mycophenolate mofetil (MMF) represents a derivative of MPA, with greater bioavailability, improved tolerance, and enhanced immunosuppression.

MECHANISM OF ACTION MMF acts as a noncompetitive inhibitor of inosine monophosphate dehydrogenase. Inhibition of this enzyme prevents conversion of inosine-5-phosphate and xanthine-5-phosphate to guanosine-5-phosphate, a precursor of DNA and RNA synthesis. MMF interferes with de novo purine synthesis, and, consequently, it is cytotoxic to cells that lack a purine salvage pathway, specifically T and B lymphocytes.[52] Selective targeting of lymphocytes facilitates the immunosuppressive properties of MMF.

PHARMACOKINETICS After ingestion, MMF is quickly converted to MPA via pre-systemic metabolism. In the liver, resultant MPA is glucoronidated into an inactive compound (MPAG). Specialized tissues, such as the lining of the gastrointestinal tract and the epidermis, possess β-glucuronidase activity that converts MPAG back into the active form. Any unconverted MPAG is excreted by the kidney.

INDICATIONS In dermatology, MMF is used for a variety of "off-label" indications. It has been used both for psoriasis and also as a steroid-sparing agent in autoimmune blistering disorders, such as pemphigus vulgaris, pemphigus foliaceus, and bullous pemphigoid (Table 228-9).[53] Success using MMF has also been reported in pyoderma gangrenosum,[54] systemic vasculitis, dihydrotic eczema, metastatic Crohn disease, dermatomyositis, cutaneous lupus, and severe lichen planus. Topical MPA has improved experimentally induced allergic contact dermatitis.

TABLE 228-9
Uses for Mycophenolate Mofetil in Dermatology

- U.S. Food and Drug Administration–approved indications
  - None
- "Off-label" uses
  - Severe psoriasis (but ineffective for psoriatic arthropathy)
  - Pemphigus vulgaris
  - Pemphigus foliaceus
  - Dermatomyositis
  - Severe cutaneous lupus erythematosus
  - Refractory pyoderma gangrenosum
  - Sarcoidosis
  - Severe dyshidrotic dermatitis
  - Severe lichen planus
  - Metastatic Crohn disease

TABLE 228-10
Safety Monitoring for Mycophenolate Mofetil Use

- Initial evaluation
  - Careful history and physical examination
  - Survey for interacting medications (antacid use, cholestyramine)
  - Baseline laboratories:
    - CBC with differential/platelets
    - Basic serum chemistry profile
    - Liver function tests
    - Tuberculin testing (if indicated)
- Ongoing laboratory monitoring
  - CBC with differential/platelets
    - Perform weekly to biweekly for first month, then
      - ~ Increase to biweekly for 2–3 mo, then
      - ~ Discontinue therapy if white blood cell count < 4000/mm^3
  - Liver function testing
    - Monthly
- Follow-up clinical evaluation
  - Biannual complete physical examinations

CBC = complete blood cell count.

DOSAGE REGIMEN MMF is available as 250-mg capsules, 500-mg tablets, or a powder for reconstitution as a suspension (200 mg/mL). Recently, a 720-mg, enteric-coated tablet of mycophenolate sodium (Myfortic™) was released. The enteric coating is designed to delay release until it reaches the small intestine; it provides the therapeutic equivalent of standard 1000-mg dosing.[55]

Typically a dose of MMF of 1.5 g/day to 2 g/day is utilized for cutaneous disease. Occasionally, doses of 3.0 to 4.0 g/day have been employed for severe disease. In general, daily doses of 2 g or less are better tolerated, with fewer adverse effects.

INITIATING THERAPY All patients should receive a complete history and physical examination before dosing. Patients with severe co-morbidities, active infections, or the possibility of reactivation of infection should be excluded from treatment with MMF. There are multiple reports of reactivation of tuberculosis in transplant patients after conversion to MMF from azathioprine, suggesting that tuberculin screening is prudent.[56,57] Baseline laboratory studies should include a CBC with manual differential and platelet count, serum chemistry profile, and liver function studies.

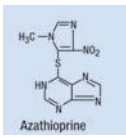
TABLE 228-11
Risks and Precautions with Mycophenolate Mofetil Use

- Absolute contraindications
  - Hypersensitivity to mycophenolate; polysorbate 80 (in intravenous formulation)
- Relative contraindications
  - Pregnancy/lactation (Category C)
  - Severe hepatic or renal disease
  - Peptic ulcer disease (possible increased risk of gastrointestinal perforation)
- Common adverse effects
  - Gastrointestinal
    - Most common; dose-dependent and diminish with continued use
    - Includes nausea, diarrhea, abdominal cramps, vomiting, anal tenderness
  - Genitourinary
    - Includes urinary urgency, frequency, dysuria, even sterile pyuria
    - No frank nephrotoxicity
  - Infectious
    - Increased incidence of herpes zoster
    - Increased incidence of opportunistic infection in renal transplant patients using ≥ 2.0 g/day
  - Neurologic
    - Headache, weakness, fatigue, tinnitus, and insomnia

MONITORING THERAPY Guidelines for monitoring MMF therapy include a CBC with differential and platelet counts weekly for 1 month, biweekly for 2 to 3 months, and monthly thereafter. Monthly serum liver function tests are recommended as well. Safety guidelines used during MMF therapy are summarized in Table 228-10.

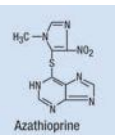
RISKS AND PRECAUTIONS Absolute and relative contraindications and common adverse effects of MMF are summarized in Table 228-11.

COMPLICATIONS MMF is generally well tolerated. Dose-dependent gastrointestinal symptoms, such as nausea, diarrhea, soft stools, anorexia, abdominal cramps, frequent stools, vomiting, and anal tenderness, are common and often diminish with time.[58] Reversible dose-related myelosuppression is possible. Genitourinary complaints with MPA, such as urgency, frequency, and dysuria, are common and are also dose dependent. MMF appears to lack significant nephrotoxicity. Herpes zoster is a common occurrence in those taking MMF. Opportunistic infections have been associated with MMF in bone marrow transplant patients with graft-versus-host disease given a median dose of 2 g/day, but limited investigation has failed to convincingly demonstrate an in-



creased risk of carcinogenesis.[59,60] Isolated reports of various cancers, such as breast cancer or squamous cancer of the head/neck, have been associated with MMF. Neurologic side effects include headache, weakness/fatigue, tinnitus, and insomnia. MMF is a Category C medication during pregnancy, and the potential for human teratogenesis is unknown; MMF is generally avoided in pregnancy.[61]

Drug Interactions. Antacids containing magnesium and aluminum hydroxide decrease absorption of MMF.[62] Anecdotal interactions between MMF and acyclovir, or its prodrug valacyclovir, have reported abrupt neutropenia; the mechanism is unknown. Cholestyramine decreases blood levels of MPA, possibly through the interruption of enterohepatic recirculation.



Azathioprine

Thioguanine

Thioguanine (see Fig. 228-1) is a lesser utilized member of the thiopurine family of drugs. It has a metabolism and mechanism of action similar to that of azathioprine.

MECHANISM OF ACTION Thioguanine is a prodrug that produces nucleoside analogues through the action of purine nucleoside phosphorylases present in tissues. These guanine analogues undergo enzymatic conversion to nucleotides and ultimately yield cytotoxic activity via incorporation into cellular DNA. Apoptosis is induced preferentially against activated T lymphocytes. The clinical response to thioguanine has been correlated to decreased T lymphocyte counts in psoriatic skin lesions, irrespective of systemic lymphocyte counts.[63]

PHARMACOKINETICS Thioguanine is administered orally, but it has incomplete and unpredictable absorption. Peak plasma concentrations may vary 10-fold and occur 2 to 4 hours after ingestion.[64]

INDICATIONS In dermatology, thioguanine is used chiefly for the treatment of psoriasis, particularly in those with recalcitrant disease or with contraindications to other systemic therapies. (Table 228-12). In a recent retrospective study of patients with recalcitrant psoriasis, 14 of 18 patients experienced greater than 90 percent improvement with thioguanine, including patients with psoriatic arthritis, palmoplantar disease, or scalp involvement.[65] Thioguanine has been used effectively, although infrequently, to treat lupus and atopic dermatitis.

TABLE 228-12
Uses for Thioguanine in Dermatology

- U.S. Food and Drug Administration–approved indications
  - None
- "Off-label" uses
  - Severe psoriasis
  - Severe cutaneous lupus erythematosus
  - Severe atopic dermatitis

DOSING REGIMEN Thioguanine is supplied as 40-mg tablets. Classically, treatment was initiated with a 40 mg/day dose, with close monitoring for myelosuppression. After 1 month, if the clinical response was inadequate, the dose was increased to 80 to 120 mg/day. A pulsed regimen of 100 mg to 120 mg twice weekly, increasing up to 160 mg three times per week, has been reported effective.[66]

Similar to azathioprine, use of commercial assays for TPMT activity improve thioguanine dosing. The latest review of thioguanine use in severe psoriasis recommends an assessment of TPMT levels before treatment so as to guide the selection of an adequate starting dose.[65] Patients with high levels of TPMT expression can likely begin with 80 mg/day from the start.

INITIATING THERAPY All patients should undergo a thorough history and physical examination before initiation of treatment. Patients with severe comorbidities, particularly hematologic disturbances, or active infection should be excluded. Women of childbearing age should receive a pregnancy test. Recommended baseline laboratory studies include a CBC with manual differential and platelet count, liver function studies, and a TPMT activity assay.

MONITORING THERAPY Repeat blood counts and liver function tests should be followed weekly at first, transitioning to biweekly as the dose stabilizes, then monthly for 3 months, and quarterly thereafter. Always perform laboratory testing when a dose is escalated. Safety guidelines used during thioguanine therapy are summarized in Table 228-13.

RISKS AND PRECAUTIONS Absolute and relative contraindications and common adverse effects of thioguanine are summarized in Table 228-14.

COMPLICATIONS Common adverse effects of thioguanine include myelosuppression and gastrointestinal disturbances. In the largest series of patients using thioguanine for psoriasis, just less than one-half experienced myelosuppression, yet only 20 percent required complete discontinuance.[67] In one series, thrombocytopenia was the earliest indicator of myelosuppression.[65] Pulsed dosing of thioguanine has been associated with a lower rate of myelosuppression, but, admittedly, TPMT testing was not performed in this study.[66]

Gastrointestinal disturbances include nausea, excessive flatulence, taste changes, esophageal reflux, and diarrhea, symptoms that are often tolerated without discontinuance. In a single study, elevated liver transaminases occurred in 25 percent of patients, yet many had been

TABLE 228-13

  - CBC with differential/platelets
  - Liver function tests
  - Renal function testing (creatinine/blood urea nitrogen)
- Ongoing laboratory monitoring
  - CBC with differential/platelets and liver function tests
    - Perform weekly initially, then
      - ~ Transition to biweekly as the dose stabilizes, then
      - ~ Monthly for 3 mo and quarterly thereafter
      - ~ Perform laboratory testing with any dose escalation

CBC = complete blood cell count.

TABLE 228-14
Risks and Precautions with Thioguanine Use

- Absolute contraindications
  - Hypersensitivity to thioguanine
- Relative contraindications
  - Pregnancy/lactation (Category D)
  - History of hepatovenular occlusive disease
  - Hematologic disorders
- Common adverse effects
  - Myelosuppression (most common side effect)
  - Gastrointestinal distress (often tolerated)
  - Toxic hepatitis (less common than with other cytotoxic agents)

taking methotrexate before the study.[67] Generally, thioguanine is not considered particularly hepatotoxic; liver biopsy is not indicated during treatment. Rare cases of toxic hepatic venoocclusive disease have been described in patients using thioguanine for psoriasis.[68] Low-dose thioguanine use in pregnant women has been reported with inflammatory bowel disease; however, use during pregnancy is generally avoided.[69]

Drug Interactions. Thioguanine metabolism is not dependent on XO; it may be administered concurrently with allopurinol without dose reduction. Aminosalicylates may inhibit TPMT activity, and it may be prudent to minimize or avoid such medications in patients taking thioguanine.

Hydroxyurea

Hydroxyurea was first synthesized in 1869, and through the years it has been used to treat a variety of conditions, including hematologic malignancies, sickle cell anemia, and psoriasis.

MECHANISM OF ACTION Hydroxyurea impairs DNA synthesis through inhibition of ribonucleotide diphosphate reductase, an enzyme that reduces nucleotides to deoxynucleotides. This inhibition limits the supply of DNA bases available for synthesis. Strand breakage and cell death result. Hydroxyurea also prevents cells from repairing damage from UV or ionizing radiation, acting as a radiosensitizer. Finally, hydroxyurea yields hypomethylation of genes, altering expression,[70] and this may contribute to normalization of psoriatic skin through improved keratinocyte differentiation. Hydroxyurea is most active in cells with a high proliferative index. It is preferentially concentrated within leukocytes.

PHARMACOKINETICS Hydroxyurea is a small molecule that is well absorbed after oral administration. Serum levels peak within 2 hours of dosing. Hydroxyurea has a rapid onset of action, with tissue effects noted within 5 hours. The actual metabolism of hydroxyurea is incompletely understood, but at least 80 percent is excreted by the kidney. Within 24 hours of dosing, negligible amounts hydroxyurea remain in the body.

INDICATIONS In dermatology, hydroxyurea is used chiefly for treatment of psoriasis (Table 228-15). Efficacy has been demonstrated in plaque, pustular, and erythrodermic forms. Still others believe hydroxyurea is only moderately effective and prefer to reserve use as a maintenance therapy once initial clearance has been achieved via other modalities.

TABLE 228-15
Uses for Hydroxyurea in Dermatology

- U.S. Food and Drug Administration–approved indications
  - Squamous cell carcinoma of the head and neck (rare use)
  - Metastatic melanoma and gastrointestinal melanoma (rare use)
- "Off-label" uses
  - Severe psoriasis (often an option for those with liver disease that limits other options)
  - Pyoderma gangrenosum
  - Sweet syndrome
  - Cryoglobulinemia
  - Scleromyxedema
  - Hypereosinophilic syndrome

In a large series of 60 patients treated with hydroxyurea for severe psoriasis, 50 percent to 60 percent achieved a response.[71] When hydroxyurea is effective, a response generally occurs within 2 to 3 weeks, with maximal improvement at 6 to 8 weeks. Because hydroxyurea has relatively little hepatic toxicity, it may be a viable alternative for those with liver disease, which precludes use of methotrexate.

DOSING REGIMEN Hydroxyurea is available as 500-mg tablets. Typical doses range from 1 to 2 g daily, usually as a divided dose. Doses above 2 g daily are unlikely to yield additional benefit and are increasingly toxic.[72] Hydroxyurea is usually well tolerated, but if dyspepsia occurs, the medication may be taken with food, milk, or antacids.

INITIATING THERAPY Patients placed on hydroxyurea should have a complete history and physical examination. Exclusion of patients with severe co-morbidities or active infections is often indicated. All women of childbearing age should receive a pregnancy test. Baseline laboratory evaluation should include a CBC with manual differential and platelet count, a serum chemistry evaluation, and urinalysis. Older patients and those with renal impairment are more susceptible to toxicity with hydroxyurea and should receive starting doses of only 500 mg/day.

MONITORING THERAPY CBCs should be repeated weekly during early therapy; this may be increased to biweekly, and, later, to monthly if results remain stable.

TABLE 228-16
Safety Monitoring for Hydroxyurea Use

- Initial evaluation
  - Careful history and physical examination
  - Identification of proper patient characteristics and risk factors
  - Survey for interacting medications (cytarabine)
  - Baseline laboratories:
    - CBC with differential/platelets
    - Basic serum chemistry profile
    - Urinalysis
    - Renal function testing (creatinine/blood urea nitrogen)
- Ongoing laboratory monitoring
  - CBC with differential/platelets
    - Perform weekly initially, then
      - ~ Transition to biweekly or monthly after 1 mo
      - ~ Perform testing with any dose escalation
      - ~ Decrease/discontinue if hemoglobin decreases by 3 g/dL, white blood cell count < 4000/mm^3, or platelets < 100,000/mm^3
  - Serum chemistry and urinalysis
    - Perform monthly initially, then
      - ~ Transition to every 3–6 mo if stable
      - ~ Perform testing with any dose escalation

CBC = complete blood cell count.

Liver function studies and urinalysis should be monitored monthly. Close surveillance for non-melanoma skin cancer at follow-up visits is indicated. Discontinuance of hydroxyurea is indicated if a satisfactory response is not achieved with 8 weeks of therapy. Safety guidelines used during hydroxyurea therapy are summarized in Table 228-16.

RISKS AND PRECAUTIONS Absolute and relative contraindications and common adverse effects of hydroxyurea are summarized in Table 228-17.

COMPLICATIONS In one large study of hydroxyurea for psoriasis, 57 percent of those who received 1.5 g/day of hydroxyurea experienced no side effects, and only 18 percent discontinued therapy because of adverse effects.[73] The most common adverse effect with hydroxyurea is myelosuppression. Mild megaloblastic changes are ubiquitous among patients receiving hydroxyurea and are not a reason for discontinuance. Frank anemia is present in 12 percent to 34 percent of treated patients, leukopenia in 7 percent, and thrombocytopenia in 2 percent to 3 percent. Myelosuppres-

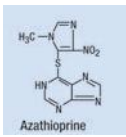

TABLE 228-17
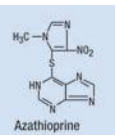
Risks and Precautions with Hydroxyurea Use

- Absolute contraindications
  - Hypersensitivity to hydroxyurea
- Relative contraindications
  - Pregnancy/lactation (Category D)
  - History of hepatovenular occlusive disease
  - Chronic anemia
  - Renal disease
- Common adverse effects
  - Myelosuppression (most common side effect)
  - Dermatomyositis-like drug eruption
  - Renal toxicity (elevated creatinine/blood urea nitrogen, hematuria, proteinuria)
  - Increased risk of secondary hematologic malignancies when used for polycythemia vera



Azathioprine

sion due to hydroxyurea usually resolves rapidly on discontinuance.

Patients taking hydroxyurea may experience a variety of cutaneous side effects, including a dermatomyositis-like eruption,[74,75] a lichenoid drug eruption, leg ulcers, alopecia, photosensitivity with radiation recall, and hyperpigmentation of the skin and nails. In patients treated with hydroxyurea for myeloproliferative disorders, non-melanoma skin cancer has been reported as an association.[76,77] It is unclear if this represents a true risk factor for those treated for cutaneous disease or if confounding circumstances exist.

Other reported side effects of hydroxyurea include lupus erythematosus, mild gastrointestinal distress, and secondary malignancies when used in patients with primary hematologic disorders, such as polycythemia vera. A rare but important adverse effect of hydroxyurea is fever with a flu-like illness. Hydroxyurea is a Category D agent during pregnancy, and use is generally avoided. There is a single report of hydroxyurea use for polycythemia vera during pregnancy without any apparent fetal or neonatal complications.[78]

Drug Interactions. Hydroxyurea appears to have few significant drug interactions, with the exception of co-administration with other myelosuppressive agents and cytarabine. Use of such agents with hydroxyurea may lead to additive bone marrow toxicity.

ALKYLATING AGENTS

Cyclophosphamide

Cyclophosphamide (see Fig. 228-1) is a derivative of nitrogen mustard, and it acts primarily by cross-linking DNA. In oncology, cyclophosphamide is used as an antineoplastic agent. In dermatology, it is used as an immunosuppressive and steroid-sparing agent, particularly for autoimmune blistering disorders and systemic vasculitis.

MECHANISM OF ACTION Cyclophosphamide is a classic cell-cycle non-specific drug; its cytotoxic effect is independent of the proliferative index. Active metabolites of cyclophosphamide form covalent bonds with the nucleophilic centers of DNA. This alkylation leads to DNA cross-linking, abnormal base-pair formation, imidazole ring cleavage with depurination, and chain scission. Ultimately, these mutations lead to cell death and possibly mutagenesis and carcinogenesis. Cyclophosphamide has a greater effect on B lymphocytes than T lymphocytes and a greater effect on suppressor T cells than helper T cells.[79] Resistance to cyclophosphamide may occur due to decreased cellular penetration, increased competition from other nucleophilic substances, improved DNA repair, or increased drug metabolism.

PHARMACOKINETICS Oral cyclophosphamide has a bioavailability of 74 percent. Peak plasma levels are achieved within 1 hour of administration. The half-life of the drug is between 2 and 10 hours. Cyclophosphamide undergoes hepatic metabolism via the cytochrome P_{450} system.[80] It is first converted to 4-hydroxycyclophosphamide, an active molecule that exists in equilibrium with aldophosphamide. Aldophosphamide may be cleaved to phosphoramide mustard, another active metabolite, and acrolein, an inactive metabolite. Aldehyde dehydrogenase may also convert aldophosphamide into a second inactive metabolite, carboxyphosphamide. The kidneys excrete just 10 percent to 20 percent of the drug unchanged but excrete 50 percent of the active metabolites.

INDICATIONS In dermatology, cyclophosphamide is used chiefly as a steroid-sparing agent for life-threatening diseases (Table 228-18). In particular, pemphigus vulgaris may be treated with cyclophosphamide in combination with steroids. Cyclophosphamide has also been used for the treatment of cicatricial pemphigoid and has been cautiously and inconsistently reported as beneficial in Stevens-Johnson syndrome and toxic epidermal necrolysis.[81,82]

Survival of patients with many forms of vasculitis has been improved with combination therapy with cyclophosphamide and steroids.[83] Diseases such as Wegener granulomatosis, Churg-Strauss syndrome, polyarteritis nodosa, and lymphomatoid granulomatosis often require cyclophosphamide therapy. Other diseases that may respond to cyclophosphamide include lupus erythematosus, Behçet disease, pyoderma gangrenosum, lichen planus, and lichen myxedematosus; yet, with the availability of safer immunosuppressive agents, cyclophosphamide is not a typical choice for nonlethal inflammatory diseases.

TABLE 228-18
Uses for Cyclophosphamide in Dermatology

- U.S. Food and Drug Administration–approved indications
  - Mycosis fungoides (advanced disease)
- "Off-label" uses
  - Wegener granulomatosis
  - Lymphomatoid granulomatosis
  - Polyarteritis nodosa
  - Severe and recalcitrant leukocytoclastic vasculitis
  - Dermatomyositis
  - Scleroderma
  - Relapsing polychondritis
  - Severe cutaneous lupus erythematosus
  - Pemphigus vulgaris
  - Bullous pemphigoid
  - Pyoderma gangrenosum
  - Scleromyxedema/lichen myxedematosus
  - Multicentric reticulohistiocytosis
  - Cytophagic panniculitis
  - Severe and recalcitrant eczematous conditions

DOSING REGIMEN Cyclophosphamide is available as 25- and 50-mg tablets and also as an injectate. Oral doses are typically 1 to 3 mg/kg/day either divided or as a single morning dose. Intravenous pulse dosing of 0.5 to 1.0 g/m^2 monthly may be associated with fewer side effects than daily oral dosing. Vigorous hydration, beginning 24 hours before and continuing throughout therapy, is recommended to reduce bladder toxicity.

INITIATING THERAPY Patients being considered for cyclophosphamide therapy should have a thorough history and physical examination. Cyclophosphamide is contraindicated in patients with a history of transitional cell carcinoma of the bladder.[84] Patients with a history of a lymphoproliferative disorder must be treated with extreme caution. Use in pregnant or lactating patients is contrain-

dicated. Baseline laboratory evaluations include a CBC with manual differential, serum chemistry profile, liver function testing, and urinalysis. Initiation of cyclophosphamide therapy is often contraindicated if the total white blood cell count is less than 5000/mm^3 or if the granulocyte count is less than 2000/mm^3.

MONITORING THERAPY Blood counts and urinalysis should be repeated weekly but may be reduced to biweekly or monthly over 2 to 3 months. Liver function testing should continue monthly but may be reduced to every 3 months if stable. Urine cytology is indicated when the cumulative dose exceeds 50 g and every 6 months thereafter, or on any occasion of hemorrhagic cystitis. Some authorities recommend a chest x-ray every 6 months. Follow-up physical examination should pay particular attention to any evidence of lymphoproliferative disease (lymphadenopathy). Patients taking cyclophosphamide should have all age-appropriate cancer screening, including stool guaiac examination and Papanicolaou smears for women. Safety guidelines used during cyclophosphamide therapy are summarized in Table 228-19.

RISKS AND PRECAUTIONS Absolute and relative contraindications and common adverse effects of cyclophosphamide are summarized in Table 228-20.

COMPLICATIONS Because of its activity independent of the cell cycle, the toxic effects of cyclophosphamide are significant and numerous.

Gastrointestinal Effects. Nausea and vomiting are the most common gastrointestinal side effects associated with cyclophosphamide use. Co-administration of ondansetron and dexamethasone reduces these side effects. The addition of aprepitant to this combination therapy may provide even greater antiemetic action.[85]

Hematologic Effects. Hematologic disturbances are frequent with cyclophosphamide, especially leukopenia and thrombocytopenia. A nadir in blood counts occurs 8 to 12 days after initiation of therapy. Myelosuppression is not requisite to immunosuppression, but it often represents a dose-limiting side effect.

Genitourinary Effects. Bladder toxicity is a well-recognized consequence of cyclophosphamide use. Hemorrhagic cystitis occurs in 5 percent to 40 percent of patients treated with oral cyclophosphamide.[86] This cystitis occurs during therapy and is believed to be caused by the metabolite, acrolein. A scavenging agent, mesna (sodium 2-mercaptoethane sulfonate), binds acrolein in the bladder and reduces irritation. Mesna is used primarily with high-dose cyclophosphamide regimens, but it may be used in low-dose therapy as well.[87] It may be administered orally or intravenously and may cause a maculopapular drug rash in some patients. Hemorrhagic cystitis and untreated bladder toxicity are thought responsible for the markedly increased risk of transitional cell carcinoma of the bladder (8- to 10-fold increased risk) among those taking chronic cyclophosphamide. Bladder cancer may arise years after therapy, and continued monitoring of the lower urinary tract is indicated.

TABLE 228-19
Safety Monitoring for Cyclophosphamide Use

- Initial evaluation
  - Careful history and physical examination
  - Identification of proper patient characteristics and risk factors
  - Survey for interacting medications (allopurinol, cimetidine)
  - Baseline laboratories:
    - CBC with differential/platelets
    - Basic serum chemistry profile
    - Urinalysis
    - Renal function testing (creatinine/blood urea nitrogen)
- Ongoing laboratory monitoring
  - CBC with differential/platelets and urinalysis
    - Perform weekly initially, then
      - ~ Transition to biweekly or monthly after 2–3 mo
      - ~ Perform testing with any dose escalation
      - ~ Decrease/discontinue if white blood cell count < 4000/mm^3, or platelets < 100,000/mm^3
      - ~ Discontinue and refer to urologist if red blood cells appear in urine
  - Basic serum chemistry and liver function tests
    - Perform monthly initially, then
      - ~ Transition to every 3–6 mo if stable
  - Urine cytology testing
    - Perform when cumulative dose >50 g or if patient has hemorrhagic cystitis

CBC = complete blood cell count.

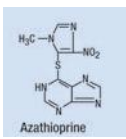
Carcinogenecity. Cyclophosphamide therapy has been associated with non-Hodgkin lymphoma, leukemia, transitional cell carcinoma of the bladder, and SCC. Much of these data involves transplant and oncology patients exposed to chronic use or higher doses, but a slight increased risk of non-Hodgkin B-cell lymphoma has been demonstrated in those treated for rheumatologic conditions as well.[88,89] The risk of cancer in those using cyclophosphamide for dermatologic conditions is likely lower than that for other indications.

TABLE 228-20
Risks and Precautions with Cyclophosphamide Use

- Absolute contraindications
  - Hypersensitivity to cyclophosphamide (can cross-react with chlorambucil)
- Relative contraindications
  - Pregnancy/lactation (Category D; fetal loss common)
  - History of transitional cell carcinoma of the bladder
  - Depressed bone marrow function
  - Impaired hepatic or renal function
- Common adverse effects
  - Gastrointestinal distress (minimized with antiemetic medications)
  - Myelosuppression (often dose limiting)
  - Hemorrhagic cystitis due to elimination of toxic metabolites (minimized with mesna)
  - Carcinogenicity (transitional cell carcinoma of bladder, lymphoproliferative disease)
  - Reproductive consequences (amenorrhea, azoospermia, gonadal failure)

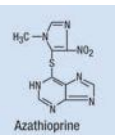
Cutaneous Effects. Anagen effluvium has been reported in 5 percent to 30 percent of those treated with cyclophosphamide.[90] In some cases, the hair loss is permanent, but generally, it is not. A permanent pigmented band on the teeth is another consequence of cyclophosphamide therapy. Diffuse hyperpigmentation of the skin and nails and acral erythema has been described. Rarely, urticaria, mucosal alterations, or induction of Stevens-Johnson syndrome have been reported.[91]

Mutagenicity and Teratogenicity. Cyclophosphamide is a Category D agent during pregnancy. A report of four pregnant women exposed to cyclophosphamide for systemic lupus resulted in uniform pregnancy loss in all cases.[92] Azoospermia and amenorrhea may also occur with cyclophosphamide use. The risk of amenorrhea has ranged from 27 percent to 60 percent of women treated, with up to 80 percent of those so affected manifesting premature ovarian failure.[93] Age and cumulative dose are most determinative of the risk of gonadal failure. In men, testosterone administration may lessen the risk of gonadal failure, whereas in women, leuprolide acetate may provide a similar partial protection.[94,95] Cryopreser-



vation of reproductive material may be used, but it is far more practical and economical for men than women. Cyclophosphamide should not be a first-line therapy for men or women who wish to conceive after treatment.

Drug Interactions. Because the microsomal enzyme system responsible for activation of cyclophosphamide is involved in the metabolism of many other drugs, the potential for multiple drug interactions exists. Allopurinol, cimetidine, and chloramphenicol all increase cyclophosphamide toxicity. The effects of succinylcholine are potentiated by cyclophosphamide. Digoxin absorption is diminished with coadministration of oral cyclophosphamide.



Azathioprine

Chlorambucil

Chlorambucil is another alkylating agent derived from nitrogen mustard. In comparison to cyclophosphamide, chlorambucil is used infrequently in dermatology.

MECHANISM OF ACTION Like cyclophosphamide, chlorambucil exerts its affects independent of the cell cycle through cross-linking of DNA.

PHARMACOKINETICS Chlorambucil is well absorbed, with 87 percent bioavailability after oral administration. The drug is 99 percent protein bound in plasma. It has a plasma half-life of approximately 1.5 hours. Less than 1 percent of the drug is excreted by the kidney. Although the drug is extensively metabolized by the liver, it does not require hepatic activation, unlike cyclophosphamide. In comparison to cyclophosphamide, chlorambucil has a slower onset of effect.

INDICATIONS Chlorambucil is rarely used in dermatology. Isolated reports detail use of chlorambucil as a steroid-sparing agent in pemphigus vulgaris, bullous pemphigoid, primary cutaneous B-cell lymphoma, aggressive pyoderma gangrenosum, and Behçet disease (Table 228-21). Interestingly, chlorambucil use has also been described in erythrodermic cutaneous T-cell lymphoma.[96] Complicating management decisions, the U.S. Food and Drug Administration–approved package insert states that chlorambucil should not be used for non-malignant diseases.

DOSING REGIMEN Chlorambucil is supplied as 2-mg tablets. The recommended dosage is 0.05 to 0.2 mg/kg/day. Doses for cutaneous disease should usually remain toward the lower end of this range.

TABLE 228-21
Uses for Chlorambucil in Dermatology

- U.S. Food and Drug Administration–approved indications
  - None
- "Off-label" uses
  - Wegener granulomatosis
  - Lymphomatoid granulomatosis
  - Dermatomyositis
  - Scleroderma
  - Relapsing polychondritis
  - Severe cutaneous lupus erythematosus
  - Pemphigus vulgaris
  - Bullous pemphigoid
  - Epidermolysis bullosa acquisita
  - Pyoderma gangrenosum
  - Scleromyxedema/lichen myxedematosus
  - Langerhans cell histiocytosis
  - Mycosis fungoides/Sézary syndrome
  - Necrobiotic xanthogranuloma with paraproteinemia
  - Sarcoidosis
  - Severe disseminated granuloma annulare

INITIATING THERAPY Patients being considered for chlorambucil therapy should have a thorough history and physical examination. When considering chlorambucil use, patients with a history of a lymphoproliferative disorder must be approached with extreme caution. Use in pregnant or lactating patients is contraindicated. Baseline laboratory evaluations should include a CBC with manual differential, serum chemistry profile, liver function testing, and urinalysis.

MONITORING THERAPY Blood counts should be repeated weekly initially but may be reduced to biweekly or monthly with time. Liver function testing and urinalysis should continue monthly but may be reduced to every 3 months if stable. Some authorities recommend a chest x-ray every 6 months. Follow-up physical examination should pay particular attention to any evidence of lymphoproliferative disease (lymphadenopathy). Patients taking chlorambucil should have all age-appropriate cancer screening, including stool guaiac examinations and Papanicolaou smears for women. Safety guidelines during chlorambucil therapy are summarized in Table 228-22.

RISKS AND PRECAUTIONS Absolute and relative contraindications and common adverse effects of chlorambucil are summarized in Table 228-23.

COMPLICATIONS Chlorambucil is considered the least toxic nitrogen mustard. Common side effects include nausea and vomiting, azoospermia, amenorrhea, pulmonary fibrosis, seizures, and hepatotoxicity. Chlorambucil increases the risk of lymphoproliferative disorders among transplant recipients. Increased SCC, particularly of the skin, has also been demonstrated in this same population. It is unclear how these risks are manifested when chlorambucil is

TABLE 228-22
Safety Monitoring for Chlorambucil Use

- Initial evaluation
  - Careful history and physical examination
  - Identification of proper patient characteristics and risk factors
  - Survey for interacting medications (vaccinations, other immunosuppressives)
  - Baseline laboratories:
    - CBC with differential/platelets
    - Basic serum chemistry profile
    - Urinalysis
    - Renal function testing (creatinine/blood urea nitrogen)
- Ongoing laboratory monitoring
  - CBC with differential/platelets and urinalysis
    - Perform weekly initially, then
      - ~ Transition to biweekly or monthly after 2–3 mo
      - ~ Perform testing with any dose escalation
      - ~ Decrease/discontinue if white blood cell count < 4000/mm^3, or platelets < 100,000/mm^3
  - Basic serum chemistry and liver function tests
    - Perform monthly initially, then
      - ~ Transition to every 3–6 mo if stable

CBC = complete blood cell count.

TABLE 228-23
Risks and Precautions with Chlorambucil Use

- Absolute contraindications
  - Hypersensitivity to chlorambucil (can cross-react with cyclophosphamide)
- Relative contraindications
  - Pregnancy/lactation (Category D)
  - Active infection (dependent on severity)
  - Impaired hepatic function
  - Childhood (may have increased risk of seizures)
- Common adverse effects
  - Myelosuppression (often dose-limiting)
  - Gastrointestinal distress (minimized with antiemetic medications)
  - Carcinogenicity (lymphoproliferative disease, squamous cell carcinoma)
  - Reproductive consequences (amenorrhea, azoospermia)

used for dermatologic disease. Other cutaneous side effects of chlorambucil include alopecia, a morbilliform rash, urticaria, and mucosal ulcerations. Chlorambucil is a Category D agent during pregnancy, and it is generally avoided in this setting.

Drug Interactions. Through strong immunosuppression, chlorambucil may decrease the efficacy of viral vaccinations. Concomitant use of additional immunosuppressive drugs may potentiate any risk of infection or carcinogenesis.

Anthracyclines

Anthracyclines are antibiotic molecules that possess potent antineoplastic properties. These agents act specifically during the S phase of cell division. Pegylated liposomal doxorubicin (PLD) (see Fig. 228-1) is an anthracycline sometimes employed in dermatology for the treatment of Kaposi sarcoma.[97]

MECHANISM OF ACTION Anthracyclines, such as doxorubicin, are intercalated within DNA and RNA. Through template disorder and steric obstruction, this incorporation leads to defective synthesis. Cell death typically results, but mutagenesis and carcinogenesis may also occur.

PHARMACOKINETICS PLD has pharmacokinetic properties similar to standard doxorubicin; however, the liposomal formulation results in improved tolerance. Encapsulating liposomes have a diameter of approximately 100 nm and are designed to prevent phagocytosis of the agent by the reticuloendothelial system. The result is a plasma half-life of more than 55 hours and improved tumor penetrance.

INDICATIONS PLD is approved by the U.S. Food and Drug Administration for the treatment of acquired immunodeficiency syndrome–related (epidemic) Kaposi sarcoma.

DOSING REGIMEN PLD is administered at a dose of 20 to 30 mg/m^2 infused intravenously over 30 to 60 minutes once every 2 to 3 weeks.

INITIATING THERAPY A thorough history and physical examination is required before initiation of therapy with PLD. Prior use of anthracyclines is an indication for caution, as additive cardiotoxicity may occur. Physical evidence of existing cardiac failure should be sought.

TABLE 228-24
Risks and Precautions with Doxorubicin Use

- Absolute contraindications
  - Hypersensitivity to anthracyclines
- Relative contraindications
  - Pregnancy/lactation (Category D)
- Common adverse effects
  - Myelosuppression
  - Gastrointestinal distress
  - Toxic hepatitis
  - Hyperpigmentation of the skin and nails

Baseline laboratory studies should include a CBC with manual differential and platelet count, a CD4 count, an HIV viral load assay, and liver function studies, including a total bilirubin.

MONITORING THERAPY Before each dose of PLD, all patients should have a repeat blood count, CD4 count, and liver function tests with total bilirubin. Specific tests for cardiotoxicity, such as a multiple-gated acquisition scan, are indicated for cumulative doses greater than 450 mg/m^2 or if signs or symptoms of congestive heart failure develop.

RISKS AND PRECAUTIONS Absolute and relative contraindications and common adverse effects of doxorubicin are summarized in Table 228-24.

COMPLICATIONS Myelosuppression is the most common side effect of PLD. A nadir in blood counts is expected during the second week of therapy. Any resultant neutropenia should be treated aggressively with granulocyte-macrophage colony-stimulating factor or granulocyte colony-stimulating factor. Characteristically, the HIV viral load does not change substantially during treatment, but CD4 counts may be lowered slightly. Abrupt or precipitous decreases in a CD4 count may be a reason to suspend treatment.

Although it is presumed that PLD has myocardial toxicity, it would appear less cardiotoxic in comparison to non-liposomal forms of doxorubicin. Although many still encourage testing for congestive heart failure with cumulative doses in excess of 450 mg/m^2, multiple studies have shown no adverse cardiac impact with cumulative doses of up to 1040 mg/m^2. Hepatotoxicity has been described with PLD, and this may be additive to any such toxicity caused by antiretroviral medications. Nausea and vomiting with dosing is also common. Doxorubicin is a Category D agent during pregnancy. It is embryotoxic and an abortifacient and should be avoided in women who are pregnant or who are planning to conceive during treatment.

A small percentage of patients may experience an initial infusion reaction, which typically resolves and does not occur with later dosing. Other cutaneous effects include hyperpigmentation of the skin and nails, alopecia, acral erythema and dysesthesias, urticaria, radiation recall reactions, or a pustular psoriasiform drug eruption.

Drug Interactions. To date, no drug interaction studies have been conducted with PLD, but it is reasonable to conclude it may interact with drugs known to interact with conventional doxorubicin, specifically digoxin, cyclosporine, calcium channel blockers, and ciprofloxacin, to name a few.

Despite continued introduction of highly targeted immunomodulating drugs ("biologics") (see Chap. 235), cytotoxic agents remain as important medications in the therapeutic arsenal of dermatologists. Table 228-25 summarizes the major indications, principal mechanism of action, and common toxicities of these agents.

MUCOCUTANEOUS REACTIONS TO CYTOTOXIC AGENTS

Specific cytotoxic agents may be used by dermatologists for treatment of severe and recalcitrant dermatologic disease, but typically only certain agents are employed, and dosages are typically less than those used for other indications. Mucocutaneous reactions to these medications initiated by other providers are commonly seen in patients during consultation. A morphologic approach to those reactions is useful. To this end, subcategories of mucocutaneous reactions to various cytotoxic agents are examined, paying particular attention to those that may provoke characteristic mucocutaneous reactions.

Hair Follicle Complications

ALOPECIA One of the most widely recognized cutaneous effects of cytotoxic agents is alopecia, often creating great distress within the patient. Cytotoxin-induced alopecia is typically a form of anagen effluvium caused by interruption of the rapidly dividing cells of the hair matrix. The particular agent, dose, schedule, and route of administration impact the degree of hair loss, yet, at equivalent dosages, intravenous administration is

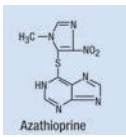


TABLE 228-25
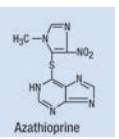
Summary of Cytotoxic Agents Commonly Used in Dermatology

Drug	Common Indications	Mechanism of Action	Typical Dose	Key Side Effects
Methotrexate	Psoriasis Connective tissue disease	Inhibition of dihydrofolate reductase	10.0–17.5 mg/wk	Myelosuppression Toxic hepatitis Liver fibrosis/cirrhosis
Azathioprine	Bullous disorders Connective tissue disease	Forms purine analogues that interrupt DNA/RNA synthesis	0.5–2.5 mg/kg/day (dependent on innate TPMT expression)	Myelosuppression Gastrointestinal distress Increased risk of malignancy
Mycophenolate mofetil	Psoriasis Connective tissue disease	Inhibition of inosine monophosphate dehydrogenase	1.5–2.0 g/day	Gastrointestinal distress Myelosuppression
Thioguanine	Psoriasis	Forms purine analogues that interrupt DNA/RNA synthesis	80–120 mg/day or 120–160 mg 3×/wk (dependent on innate TPMT expression)	Myelosuppression
Hydroxyurea	Psoriasis	Inhibition of ribonucleotide diphosphate reductase	1–2 g/day	Myelosuppression Dermatomyositis-like reaction
Cyclophosphamide	Vasculitis Connective tissue disease Advanced cutaneous T-cell lymphoma	Metabolites undergo physiochemical reactions with DNA (alkylation)	1–3 mg/kg/day or 0.5–1.0 g/monthly	Gastrointestinal distress Myelosuppression Hemorrhagic cystitis Bladder carcinogenesis
Chlorambucil	Vasculitis Connective tissue disease	Physiochemical reactions with DNA (alkylation)	0.05–0.2 mg/kg/day	Gastrointestinal distress Myelosuppression Increased risk of malignancy
Doxorubicin (liposomal)	Acquired immunodeficiency syndrome–related Kaposi sarcoma	Intercalation into DNA with termination of synthesis	20–30 mg/m^2 every 2–3 wk	Gastrointestinal distress Toxic hepatitis Possible cardiotoxicity Infusion site reactions

TPMT = thiopurine methyltransferase.



generally more deleterious than oral administration. Numerous cytotoxic agents produce alopecia, but doxorubicin, cyclophosphamide, and vincristine are often implicated (Table 228-26).[98]

TABLE 228-26
Cytotoxic Agents Associated with Alopecia

- Bleomycin
- Busulfan (significant risk of permanent loss)
- Cytarabine

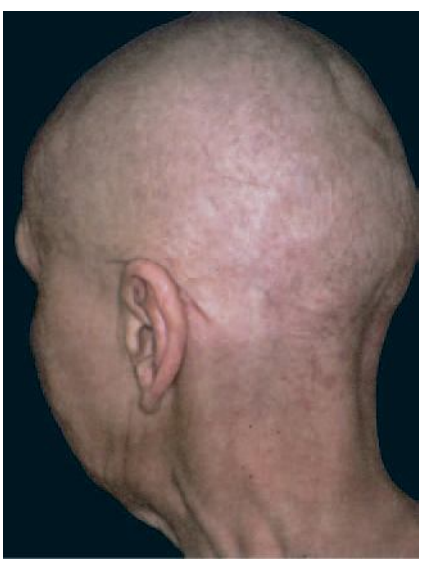
- Nitrogen mustard derivatives (**cyclophosphamide**, **chlorambucil**)
- Nitrosoureas
- Paclitaxel
- Procarbazine
- Thiotepa
- Vinca alkaloids

Agents in **bold** represent a systemic therapy not infrequently used by dermatologists in treating cutaneous illness.

Cytotoxin-induced alopecia usually begins 2 to 4 weeks after therapy and may progress for several months. Up to 85 percent to 90 percent of the hair may be lost; the remaining fraction spared is that normally in telogen. Loss of hair on the scalp and eyebrows is most noticeable, but eyelashes and body hair may be shed as well (Fig. 228-2). The alopecia typically resolves with cessation of treatment, although regrowth may occur with a different color, quality, or texture. Permanent alopecia has occurred most often with high-dose busulfan.[99] Scalp cooling has been used with limited success to minimize hair loss, likely by reducing biochemical activity, but it may create a haven for malignant cells; it remains a controversial intervention, particularly for hematologic malignancies.[100] Topical minoxidil may hasten resolution of the alopecia.[101]

FOLLICULITIS ("ACNEIFORM" ERUPTION)

Classic cytotoxin-induced folliculitis begins as erythematous macules, followed in days by the appearance of papules, and then pustules. Lesions predominate on the face and upper trunk. The eruption typically resolves over 2 weeks, but comedones may persist, or post-inflammatory hyperpigmentation may result.



▲ **FIGURE 228-2** Alopecia after the administration of combined chemotherapy with cyclophosphamide, doxorubicin, and vincristine.

- Docetaxel
- **Doxorubicin**
- Fluorouracil
- **Hydroxyurea**
- Mitoxantrone

Agents in **bold** represent a systemic therapy not infrequently used by dermatologists in treating cutaneous illness.

Simple acne vulgaris may also be aggravated by androgens used in conjunction with chemotherapeutic agents in some multidrug regimens. Folliculitis is most often associated with actinomycin D and less often with methotrexate or cisplatin.[102] Recently, a case of eosinophilic folliculitis with combined therapy with cyclophosphamide, methotrexate, and fluorouracil was reported.[103]

Nail Complications

MALFORMED NAIL PLATES (DYSTROPHY) Nail changes are often noted with cytotoxic agents (Table 228-27). Mild nail reactions produce Beau's lines. Severe reactions may produce onycholysis or onychomadesis (Fig. 228-3). The great toenail is most often affected.[104] Less common nail problems due to cytotoxic drugs include nail bed pain, thickening or thinning of the nail plate, and splinter hemorrhage or subungual hemorrhage. Anthracyclines (doxorubicin) and taxanes (paclitaxel) most often yield onychodystrophy, with paclitaxel producing nail changes in up to 40 percent of those treated.[104]

NAIL PIGMENTATION Cytotoxins may yield leukonychia or hyperpigmentation of the nail plate. Leukonychia produces a white discoloration in the nail; the mechanism is unknown, but is presumed to be cytotoxic in nature. An excellent example of patterned leukonychia are Mees' lines, which were described in 1919 as transverse white lines with arsenic exposure.[105] Cytotoxic agents that most often lead to leukonychia are doxorubicin, vincristine, cyclophosphamide, methotrexate, and 5-fluorouracil.[106]

Nail hyperpigmentation usually develops weeks or months after chemotherapy. Hyperpigmentation of the nail

▲ **FIGURE 228-3** Presence of proximal indented Beau's line and distal band of leukonychia due to cyclophosphamide 3 months after bone marrow transplantation.

may be oriented longitudinally, horizontally, diffusely, or in a perilunar fashion.[107] Various mechanisms have been proposed, including genetic predisposition, toxic effect on the nail matrix, photosensitization, or focal stimulation of melanocytes. Blacks are more often affected, presumably due to increased numbers of melanocytes within the nail matrix.[108] Cyclophosphamide, doxorubicin, hydroxyurea, and bleomycin are most often implicated in nail hyperpigmentation.[109] Typically, leukonychia or nail hyperpigmentation due to cytotoxic agents resolves with cessation of therapy.

TABLE 228-28

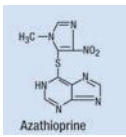
Daunorubicin	**Doxorubicin**
Doxorubicin (common)	Mitoxantrone
Mitoxantrone	Suramin
Vincristine	

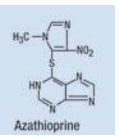
Agents in **bold** represent a systemic therapy not infrequently employed by dermatologists in treating cutaneous illness.

Eccrine Gland Complications

NEUTROPHILIC ECCRINE HIDRADENITIS Neutrophilic eccrine hidradenitis (NEH) consists of tender, erythematous macules, papules, and plaques on the trunk, neck, and extremities that develop days to months after exposure to cytotoxic agents (Fig. 228-4).[110,111] Lesions resolve spontaneously over a period of days. Histologic changes include a perieccrine neutrophilic infiltrate. Apocrine gland involvement has also been identified.[112] Concentration of the cytotoxic agent within sweat is the likely mechanism of injury. NEH is most often associated with cytarabine, but other agents have been implicated (Table 228-28). A similar condition unassociated with cytotoxic agents is recognized, suggesting the skin lesions represent a final common pathway of adnexal injury.

▲ **FIGURE 228-4** Neutrophilic eccrine hidradenitis ([illegible]). (From the Archives of Fitzsimmons Army Medical Center.)





SYRINGOSQUAMOUS METAPLASIA Chemotherapy-induced syringosquamous metaplasia (CISM) is closely related to NEH. Like neutrophilic hidradenitis, direct cytotoxic injury of sweat ducts is implicated. Clinically, CISM presents as erythematous papular eruptions, similar to miliaria, which erupt 2 to 39 days after administration of the cytotoxic agent.[113,114] The papules resolve approximately 4 weeks after discontinuance. Histologic examination demonstrates prominent squamous metaplasia of the upper sweat duct, with necrotic ductal epithelial cells; inflammation is minimal. On occasion, CISM may even mimic SCC.[115] Cytarabine has been most often associated with CISM (see Table 228-28).

Epidermal Complications

CHEMOTHERAPY-INDUCED ACRAL ERYTHEMA Multiple cytotoxic agents may yield a distinct cutaneous reaction known as *acral erythema*. The reaction usually develops 4 to 23 days after initiation of chemotherapy as painful, sharply demarcated erythema of the palmoplantar surfaces, with associated edema (Fig. 228-5).[116] In severe cases, large bullae may extend over the dorsum of the hands and feet.[117] Pain may limit ambulation or use of the hands. Therapy is limited mostly to analgesics and emollients, although pyridoxine supplementation may improve dysesthesias. The reaction is self-limited and resolves over 2 to 4 weeks. Recurrence with subsequent exposure is highly variable. The cause of acral erythema is unknown, but concentration of cytoxic agents within eccrine structures of acral skin has been proposed. In support of such a theory, coexistent syringosquamous metaplasia has been demonstrated.[118] Acral erythema is most common with cytarabine, doxorubicin, fluorouracil, and methotrexate (Table 228-29). Long-term hydroxyurea therapy may produce a unique form of acral erythema that is linear and resembles dermatomyositis, without any corresponding muscle findings (drug-induced pseudodermatomyositis); rarely, the face may be involved.[74,75]

- **Methotrexate**
- Paclitaxel
- Suramin
- Vinblastine

Agents in **bold** represent a systemic therapy not infrequently employed by dermatologists in treating cutaneous illness.

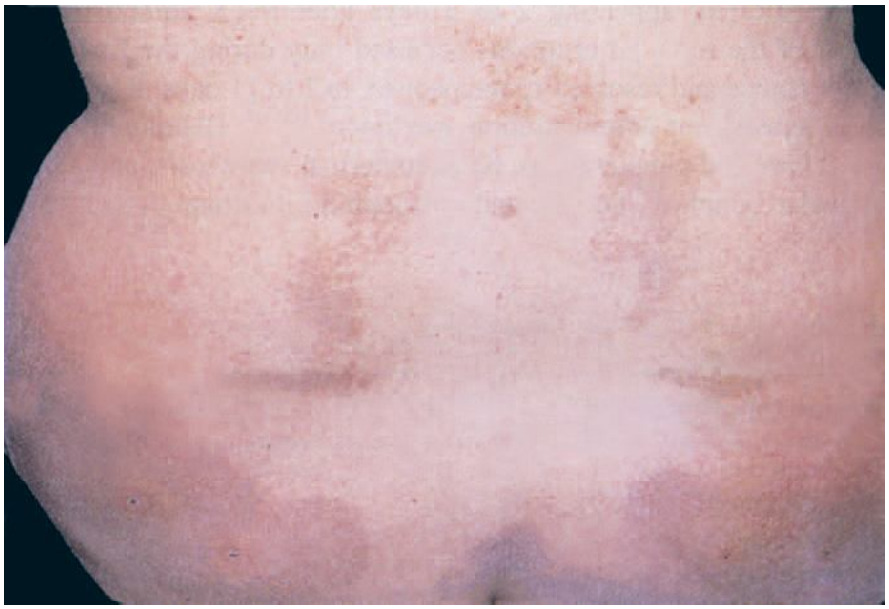
INFLAMMATION OF ACTINIC KERATOSES A number of different cytoxic agents and chemotherapeutic protocols yield inflammation of actinic keratoses. Systemic fluorouracil is the most common cause of inflamed actinic keratoses, and this should come as no surprise to dermatologists.[119] The reaction usually develops within 1 week of initiating chemotherapy. The actinic keratoses may resolve or remain after completion of the therapy. A similar reaction within seborrheic keratoses has been reported to occur with cytarabine and may mimic the sign of Leser-Trélat or herpes zoster.[120,121]

▲ **FIGURE 228-5** Cytarabine-induced painful acral erythema with edema.

▲ **FIGURE 228-6** Flagellate hyperpigmentation occurs 2 weeks after administration of bleomycin.

CUTANEOUS HYPERPIGMENTATION Bleomycin may produce a unique form of flagellate (linear) hyperpigmentation of the skin in 8 percent to 66 percent of those exposed; typically after cumulative doses of 90 to 285 mg.[122,123] Lesions begin as linear, erythematous, pruritic lesions that are slowly replaced by hyperpigmentation and are present hours to weeks after dosing (Fig. 228-6). The eruption usually resolves without treatment over weeks to months. The pathogenesis is unknown, but some investigators have induced flagellate lesions by rubbing the skin during bleomycin administration; others have been unable to replicate this result. Bleomycin may also produce patchy pigmentation in areas of pressure, within the palmar creases, or within striae distensae. Other unique forms of cutaneous hyperpigmentation are recognized, such as the serpentine supravenous hyperpigmentation that may accompany fluorouracil infusions[124] or the polycyclic bands of pigmentation on the scalp occurring with daunorubicin.[108]

Numerous antineoplastic drugs may yield other forms of hyperpigmentation, including patchy, acral, photoaccentuated, polycyclic, occlusion accentuated, pressure accentuated (Fig. 228-7), or generalized patterns (Table 228-30).[102] The cause of cutaneous hyperpigmentation is largely unknown. Postulated mechanisms include a direct toxic effect on melanocytes, increased drug deposition due to increased blood flow, local



▲ **FIGURE 228-7** Hyperpigmentation at sites of occlusion during administration of thiotepa.

toxicity due to concentration in sweat, associated endocrinologic abnormalities, and drug-induced depletion of tyrosinase inhibitors.[107]

PHOTOSENSITIVITY Most chemotherapy-induced photosensitivity is phototoxic rather than photoallergic in nature (Table 228-31; see also Chap. 91). Phototoxic reactions begin rapidly after administration and often mimic sunburns, with burning, erythema, and even vesicles or bullae. Photoallergic reactions typically present as a more eczematous process. Furthermore, photoallergic processes are dependent on sensitization and may be delayed weeks or months after an initial exposure.

TABLE 228-30
Cytotoxic Agents Associated with Skin Hyperpigmentation

DRUG	PATTERN OF PIGMENTATION
Bleomycin	Flagellate
Busulphan	Dusky, may appear similar to Addison disease
Cisplatin	Pressure-induced
Cyclophosphamide	May be localized to palms, soles, or nails
Dactinomycin	Diffuse
Daunorubicin	Sun-exposed areas
Doxorubicin	Diffuse, particularly nails
Etoposide	Occluded areas
Fluorouracil	Sun-exposed areas, areas of prior irradiation, nails
Hydroxyurea	Diffuse, particularly nails
Ifosfamide	Hands, feet, and occluded areas
Methotrexate	Sun-exposed areas, hair may develop "flag sign"
Nitrosoureas	Occluded areas
Paclitaxel	Localized
Plicamycin	Localized
Procarbazine	Diffuse
Tamoxifen	Hair pigmentation
Thiotepa	Occluded areas
Vinca alkaloids	Localized

Agents in **bold** represent a systemic therapy not infrequently employed by dermatologists in treating cutaneous illness.

RADIATION RECALL REACTION Recall reactions consist of erythema confined to an area of prior radiation exposure or sunburn. Severe cases may develop vesiculation (Fig. 228-8). True radiation recall may occur years after irradiation, and the pathogenesis is unknown. It has been postulated that radiation-damaged keratinocytes are further damaged by the administration of the cytotoxic agent (see Table 228-31).[125] Methotrexate often engenders a unique recall reaction to sunburn when dosed 1 to 3 days after exposure, although at least one case occurred as late as 8 days afterward.[126] Folinic acid supplementation (leucovorin rescue) does not prevent UV sunburn recall reactions due to methotrexate.

RADIATION ENHANCEMENT REACTIONS Radiation enhancement is a synergistic reaction between an antineoplastic agent and irradiation. This radiosensitization is often desired in antineoplastic treatment, but it may lead to adverse effects on the skin. The result may be radiation dermatitis that presents initially as pain and erythema followed by desquamation and hyperpigmentation. Although a number of chemotherapeutic agents may produce this reaction, doxorubicin and dactinomycin are most often implicated (see Table 228-31).[102]

Dermal Complications

LOCAL INJURY Extravasation of chemotherapeutic agents may occur in up to 6 percent of adults treated with infusions and is likely an even more common occurrence among pediatric patients.[107,127] As expected, the degree of injury is related to the drug used, the rate of delivery, the concentration of the agent, and the amount extravasated.

Agents with minimal toxicity on extravasation may produce only a chemical cellulitis or phlebitis and are classified as irritants. Chemical cellulitis manifests as erythema, induration, and pain at the injection site. Sometimes it may follow the course of a vein. It is often of short duration and resolves without treatment. Chemotherapy-induced phlebitis manifests as linear cords, often with accompanying discomfort.

Vesicants are agents, which on extravasation yield direct-tissue necrosis. Chemotherapy-induced tissue necrosis can be a devastating complication. Extravasation should always be treated by immediate discontinuance of the infusion and the application of either hot or cold packs. Cold packs are used for all chemotherapeutic agents except vinca alkaloids to localize the drug and promote degradation. Vinca alkaloids are treated with hot packs because application of cold promotes tissue necrosis.[128] Doxorubicin is perhaps the most dangerous of all vesicants, and extravasation of this agent may yield ulcers that progress for months that may even erode into tendon or bone (Fig. 228-9). Severe ulcerations caused by extravasation may require wide excision and skin grafting.

Other treatments advocated for specific situations include: (1) topical dimethyl sulfoxide (DMSO); (2) local injection of hyaluronidase; or (3) potent topical, intralesional, or oral steroids. DMSO is a topical solvent that has free-radical scavenging and antioxidant properties; it may hasten removal of extravasated drugs. Studies suggest that topical DMSO may have benefit in anthracycline-induced skin ulceration.[129,130] Hyaluronidase degrades hyaluronic acid, breaking down subcutaneous tissue, and promoting drug diffusion through the interstitial space. It appears effective in vinca alkaloid, epipodophyllotoxin, and paclitaxel extravasations, but should not be used in anthracycline extravasation.[131,132] Hyaluronidase is contraindicated in sites involved with malignancy or superinfection. Finally, histologic examination of extravasation injuries has demonstrated surprisingly few inflammatory cells in areas of tissue damage, perhaps explaining why corticosteroids are, in general, of little value in management.[133,134]

▲ **FIGURE 228-9** Severe tissue necrosis after extravasation of doxorubicin.

SCLEROTIC DERMAL REACTIONS Bleomycin and docetaxel produce sclerotic tissue reactions that may be localized, regional, or diffuse in extent.[135,136] Localized tissue reactions may mimic morphea or systemic sclerosis. Melphalan has been reported to produce a unique form of reticulate scleroderma after limb perfusion. The mechanism of tissue sclerosis has not been well established. Biopsies of cytoxin-induced dermal sclerosis may be indistinguishable from morphea or systemic sclerosis. In some cases, the sclerosis resolved after withdrawal of the offending agent.

RAYNAUD PHENOMENON Secondary Raynaud phenomenon, with or without digital ulceration, is most often associated with bleomycin, vincristine, cisplatin, or cisplatin with gemcitabine.[137–139] This reaction may occur with systemic chemotherapy or after intralesional injection to treat verruca vulgaris. The mechanism of development is unknown, but bleomycin is known to be toxic to endothelial cells. In a large study of 90 patients receiving bleomycin for testicular cancer, 37 percent developed Raynaud phenomenon, with 7 percent having transient disease.[137] Risk factors for the development of Raynaud phenomenon include combination therapy with vinblastine or high cumulative doses of bleomycin.

Mucosal Complications

Oral complications may occur in up to 40 percent of those receiving chemotherapy. Because of a high inherent proliferative index, the mucosa is susceptible to the effects of multiple cytotoxic agents. Young patients and those with pre-existing oral disease appear even more susceptible.[107]

TABLE 228-32
Cytotoxic Agents Associated with Mucositis

- Bleomycin
- **Cyclophosphamide**
- Cytarabine
- Dactinomycin
- Daunorubicin
- Docetaxel
- **Doxorubicin**
- Fluorouracil
- **Hydroxyurea**
- Mercaptopurine
- **Methotrexate**
- Mitomycin
- Nitrosoureas
- Paclitaxel
- Plicataxel
- Plicamycin
- Procarbazine
- Vinblastine

Agents in **bold** represent a systemic therapy not infrequently employed by dermatologists in treating cutaneous illness.

MUCOSITIS/STOMATITIS A wide range of cytoxic agents have been implicated in stomatitis (Table 228-32). Patients with cytoxin-induced stomatitis typically note burning and mucosal erythema days after administration. Painful erosions and ulcerations often follow (Fig. 228-10). The mouth is most often affected, especially the buccal mucosa and tongue, but any mucosal surface may be involved. Mucositis may be complicated by secondary bacterial or fungal infection. Meticulous, but not overly aggressive, hygiene may reduce the incidence of secondary infection, and antibiotics and antifungal agents are often used. A recent meta-analysis of treatments for chemotherapy-induced mucositis found that simple modalities, such as ice chips, had equivalent benefit to more aggressive interventions.[140] Finally, oral hemorrhage may be secondary to chemotherapy-induced thrombo-

▲ **FIGURE 228-10** Stomatitis induced by combined chemotherapy with cytarabine, doxorubicin, and methotrexate. (Used with permission from Allan C. Harrington, MD.)

cytopenia, and a careful clinical examination is always required.

MUCOSAL HYPERPIGMENTATION Many cytotoxic agents induce mucosal hyperpigmentation. Mucosal hyperpigmentation may manifest various patterns, including linear, patchy, and macular forms. Some agents tend to affect certain anatomic areas such as the gingival margin (cyclophosphamide) or tongue (fluorouracil). The mechanism of mucosal hyperpigmentation is not well understood. Typically, cytotoxin-induced hyperpigmentation resolves slowly over weeks to months after discontinuance. One notable exception is mucosal hyperpigmentation caused by cyclophosphamide, which may be permanent. Cyclophosphamide may also produce a permanent pigmented band on the teeth.

CHAPTER 229

Retinoids

Anders Vahlquist
Stéphane Kuenzli
Jean-Hilaire Saurat

Retinoids include both naturally occurring molecules and synthetic compounds that have specific biologic activities that resemble those of vitamin A or bind to the nuclear receptors for retinoids. Vitamin A from natural sources was already being used in the 1930s in high dosages to treat certain hyperkeratotic diseases, often with toxic side effects. Three generations of synthetic retinoids have since been developed (Fig. 229-1):

First generation: All-*trans* retinoic acid (tretinoin, ATRA), a naturally occurring metabolite of retinol, was the first retinoid synthesized but had no significant advantages over vitamin A in treatment of dermatologic diseases. It is used as a differentiation-inducing agent to treat acute promyelocytic leukemia.

Isotretinoin (13-*cis* retinoic acid), clinically available since the 1970s, was found to cause prolonged remissions in patients with previously treatment-resistant cystic acne [it has been approved by the U.S. Food and Drug Administration (FDA) for this indication since 1982].[1]

Second generation: Through replacement of the β-ionone ring in ATRA with an aromatic structure, newer retinoids with better therapeutic margins were synthesized in the 1970s. Etretinate and its free acid metabolite, acitretin, showed a therapeutic index 10 times more favorable than that of ATRA. Etretinate (approved in Europe 1983 and by the FDA in 1987) and acitretin (approved 1987 and 1997, respectively) became a standard treatment for psoriasis.

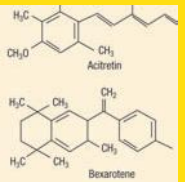
Third generation: The discovery of retinoic acid receptors (RARs)[2,3] allowed research directed toward receptor-specific, third-generation retinoids with a safer therapeutic index and a more selective action. Bexarotene, approved by the FDA in 1999 for systemic use in treating cutaneous T-cell lymphoma (CTCL), is a prime example. Bexarotene belongs to a subclass of arotinoids called *rexinoids*, because they bind to the retinoid X receptors (see Bexarotene).

MECHANISM OF ACTION

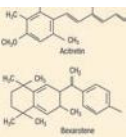
Retinoids affect cell growth and differentiation, exert immunomodulatory action, and alter cellular adhesiveness.[4] Their effect on RARs is discussed in detail in Chap. 217.

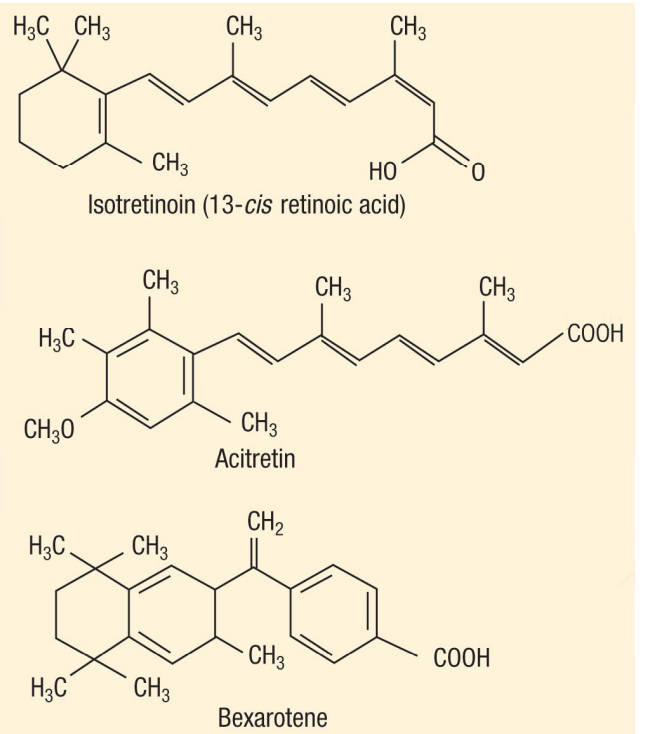
Under normal conditions, virtually all effects of vitamin A in the skin are mediated by ATRA, the cellular level of which is meticulously controlled. Endogenous ATRA has been at the focus in the development of a new class of compounds called *retinoic acid metabolism–blocking agents*, which are basically cytochrome P_{450} (CYP) enzyme 26 in-

RETINOIDS AT A GLANCE



- The biologic functions and actions of retinoids (excluding vision) include the following:
  - Reproduction, embryonic growth, and morphogenesis
  - Modulation of proliferation and differentiation of epithelia
  - Decrease in sebaceous gland size (isotretinoin)
  - Immunologic and anti-inflammatory effects
  - Tumor prevention and treatment
  - Effect on extracellular matrix components
- Three types of oral retinoids and the major indication for their use are isotretinoin (acne), acitretin (psoriasis, keratinizing disorders), and bexarotene (cutaneous T-cell lymphoma). Contraindications to their use include pregnancy, breast-feeding, and non-adherence to contraceptive regimen.
- Mucocutaneous side effects (cheilitis, xerosis, skin peeling, conjunctivitis) are common, as are reversible abnormal results on laboratory tests [hyperlipidemia, increased liver enzyme levels, and hypothyroidism (bexarotene)]. Musculoskeletal and central nervous system side effects are rare.





▲ **FIGURE 229-1** Chemical structure of three generations of retinoids. Isotretinoin is first generation; in second-generation (e.g., acitretin) the β-ionone ring, is replaced with an aromatic structure. Bexarotene is an example of a third-generation retinoid.

hibitors that impede the oxidative degradation of ATRA and thus increase the retinoid activity in target tissues.[5] Two such drugs (liarozole and Rambazole) are under development.

PHARMACOKINETICS

Isotretinoin, acitretin/etretinate, and bexarotene differ not only in their spectra of clinical efficacy but also in their toxicities and pharmacokinetics. Due to their lipophilicity, the oral bioavailability of all retinoids is enhanced when they are administrated with food, especially with fatty meals. Retinoids are metabolized mainly by oxidation and chain shortening to biologically inactive and hydrophilic metabolites, which facilitates biliary and/or renal elimination. The oxidative metabolism is induced primarily by the retinoids themselves and other agents that induce hepatic CYP isoforms.[6]

Isotretinoin

Isotretinoin and ATRA are two interconvertible isomers that differ in their elimination half-lives—approximately 20 hours for isotretinoin and 1 hour for ATRA. Isotretinoin undergoes first-pass metabolism in the liver and subsequent enterohepatic recycling. In plasma, isotretinoin is more than 99 percent bound to plasma protein, mainly albumin. It is stored in neither the liver nor adipose tissue, in sharp contrast to vitamin A and etretinate. The major metabolite is 4-oxoisotretinoin, which has reduced bioactivity; both compounds are excreted in urine and feces. After the end of treatment, endogenous concentrations of isotretinoin and its major metabolite are reached within 2 weeks. Therefore, a 1-month post-therapy period of contraception provides an adequate safety margin.[7] No clear affinity for any RARs has been identified with isotretinoin.

Acitretin and Etretinate

Etretinate is a prodrug of acitretin that undergoes extensive hydrolysis in the body to yield the corresponding acid metabolite. In animal studies and in clinical studies in patients with severe keratinizing disorders, acitretin is as effective as etretinate.[8] However, acitretin has a great pharmacokinetic advantage because it is eliminated more rapidly than etretinate.[9] Etretinate is approximately 50 times more lipophilic than acitretin and binds strongly to plasma lipoproteins, whereas acitretin binds to albumin. This fact has a profound influence on the respective pharmacokinetic properties of the two drugs.

Even when etretinate and acitretin are taken with food, the absorption of the two drugs varies.[10] Etretinate is stored in adipose tissue from which it is released slowly; it has a terminal half-life of up to 120 days. In contrast, acitretin has an elimination half-life of only 2 days.[9] However, small amounts of etretinate can be formed in patients receiving acitretin if it is taken simultaneously with alcohol.[11] This has prompted the manufacturer to extend the time of compulsory contraception in patients taking acitretin to 2 years (3 years in the United States).[12] Acitretin still has a pharmacokinetic advantage over etretinate, however, for all women who strictly avoid alcohol consumption during treatment and for 2 months thereafter.[9]

Acitretin metabolism primarily involves isomerization instead of oxidation. The major metabolite of acitretin is

its 13-*cis* isomer, which is inactive. Paradoxically, acitretin activates all three RAR sub-types but binds poorly to them.[13]

Bexarotene

Bexarotene is approximately 100-fold more potent in activating retinoid X receptors than RARs. Its absorption is particularly increased by taking it with fatty meals. In plasma, bexarotene is highly bound (more than 99 percent) to proteins that have not yet been characterized, and the ability of bexarotene to displace drugs bound to plasma proteins and the ability of drugs to displace bexarotene is unknown. Bexarotene probably has a clearance profile similar to that of isotretinoin with a terminal half-life of between 7 and 9 hours.[14] Bexarotene is metabolized by CYP 3A4 and generates its own inactive oxidative metabolites via hepatic CYP 3A4 induction. Neither bexarotene nor its metabolites are excreted in urine; elimination is thought to occur primarily via the hepatobiliary system.[15]

INDICATIONS

Acne

Isotretinoin is remarkably effective in curing acne, possibly because it affects—primarily or secondarily—all etiologic factors implicated in the pathogenesis of acne: sebum production, comedogenesis, and colonization with *Propionibacterium acnes*.[16] Of all the natural and synthetic retinoids used in humans, only isotretinoin suppresses sebum excretion and reduces sebaceous gland size.

In the early 1980s, isotretinoin treatment was restricted to patients with severe nodulocystic acne. With increasing experience, however, its use has been extended to patients with less severe disease who respond unsatisfactorily to conventional therapies such as long-term antibiotics because of the increased resistance of *P. acnes* to many antibiotics.[17,18]

Psoriasis

The retinoid of first choice for oral treatment of psoriasis is acitretin. Acitretin appears to be as effective as etretinate and can be used in the same combination regimens.[19–23] The best results have been obtained in pustular psoriasis of the palmoplantar or generalized (von Zumbusch) type.[19,24,25] Rebound does not usually occur after treatment is stopped, and reintroduction of the drug when it does occur produces a beneficial response.[26] Although complete clearing of plaque-type psoriasis is achieved in only approximately 30 percent of treated patients, significant improvement is obtained in a further 50 percent.[5,27,28] The decrease in the psoriasis area and severity index is approximately 60 percent to 70 percent, depending on the dosage.[5,8] Approximately 20 percent of patients may be considered to experience treatment failures. Combination of acitretin with other anti-psoriatic agents may then be required (see Dosing Regimens).

In a 20-week treatment study,[29] six of eleven patients (54 percent) with human immunodeficiency virus infection who had psoriasis showed good to excellent responses to acitretin monotherapy (75 mg/day). Both skin and joint manifestations responded to acitretin therapy in most patients. The adverse effects were moderate and well tolerated, and measures of immune parameters did not indicate exacerbation of immunosuppression in most patients.

Isotretinoin has less effect on psoriasis than acitretin or etretinate, although some efficacy has been shown in combination with psoralen plus ultraviolet A light (PUVA) therapy.[12] Nevertheless, some dermatologists use isotretinoin to treat women with psoriasis who need systemic retinoids to avoid the long post-acitretin contraception period required.

Cutaneous T-Cell Lymphoma

Some older studies showed that etretinate may induce clinical improvement in patients with CTCL (e.g., mycosis fungoides or Sézary syndrome) with no internal involvement; better results were obtained when etretinate was combined with PUVA treatment or interferon-α therapy. Use of the combination of acitretin or isotretinoin with oral vitamin D_3 (calcitriol) to obtain synergistic effects in the treatment of CTCL has been reported.[30,31]

In 1999 the FDA approved bexarotene as oral therapy for the treatment of CTCL that is refractory to at least one systemic therapy. In early (IA-IIA) and advanced (IIB-IVB) stages of CTCL (see Chap. 146), oral bexarotene monotherapy produced approximately 60 percent and 50 percent response rates, respectively, at a dosage of 300 mg/m^2 or more per day within the first 2 months in most patients.[32,33]

Clinical Uses Not Approved by the U.S. Food and Drug Administration

Multiple other skin disorders respond to retinoids, but for only a few of them is the effect established in controlled studies.[34] In many reports the choice of etretinate/acitretin rather than isotretinoin was based not on pharmacologic considerations but on availability of the product. Bexarotene has not been tested extensively for indications other than CTCL.

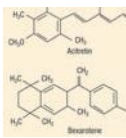
ICHTHYOSIS Among the different types of ichthyosis, the best results are obtained with acitretin for non-bullous congenital ichthyosis such as lamellar ichthyosis. Treatment of bullous ichthyosiform erythroderma (epidermolytic hyperkeratosis) may lead to an initial increase in bullae. Good results also have been achieved in treating recessive X-linked ichthyosis and ichthyosis vulgaris; however, because of its limited severity the disease often does not require retinoid therapy.

DARIER DISEASE Severe forms of Darier disease (Darier-White disease) are good indications for retinoid therapy. Care should be taken to initiate therapy with a very low dosage, such as 10 mg/day of acitretin, to prevent initial exacerbation of the disease; usually 20 mg/day is sufficient for significant improvement. Long-term treatment is usually needed to prevent relapse. Low-dose isotretinoin therapy has been used especially in women with Darier disease. Combination of retinoids with antibiotics may enhance the clinical effects, because skin lesions are frequently infected.

PITYRIASIS RUBRA PILARIS Early treatment with retinoids appears to offer the best chance for clearing of pityriasis rubra pilaris. In extensive cases, concomitant use of methotrexate may be advantageous, but this combination carries an increased risk for toxicity. Etretinate is considered to be superior to isotretinoin in the treatment of adult-onset pityriasis rubra pilaris.[35]

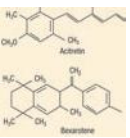
ROSACEA In severe forms or in treatment-resistant rosacea, isotretinoin therapy may be more effective for inflammatory lesions than for vascular lesions.[36] A low daily dose (10 mg) is often sufficient. The best indications are severe cases of rosacea associated with significant seborrhea.

HIDRADENITIS SUPPURATIVA Isotretinoin has limited effect on hidradenitis suppurativa, but some investigators recommend this therapy during the weeks or months preceding surgical treatment. Prolonged therapy with acitretin/etreti-



nate has been used with some success, especially in treating extensive, inflammatory lesions unsuitable for surgery.[37,38]

PRE-MALIGNANT AND MALIGNANT SKIN LESIONS Etretinate and acitretin are effective in the treatment of pre-malignant skin lesions, including human papillomavirus–induced tumors and actinic keratoses. In basal cell nevus syndrome and in xeroderma pigmentosum, these drugs reduce dramatically the incidence of malignant degeneration of the skin lesions. A double-blind study demonstrated that acitretin at a dosage of 30 mg/day for 6 months prevented the development of pre-malignant and malignant skin lesions in renal transplant recipients.[39]



LICHEN SCLEROSUS ET ATROPHICUS Acitretin/etretinate is an effective treatment for severe lichen sclerosus et atrophicus of the vulva and may be recommended intermittently for patients who are intolerant of or resistant to local therapies.[40]

LUPUS ERYTHEMATOSUS Both isotretinoin and acitretin have been used successfully in patients with various forms of lupus erythematosus. However, the lesions recur after completion of treatment as quickly as the initial improvement appeared. Acitretin and hydroxychloroquine are equally effective in the treatment of chronic discoid lupus erythematosus and subacute cutaneous lupus erythematosus.[12]

DOSING REGIMENS

Isotretinoin

The initial consensus was that optimal benefit in acne would be achieved with a high daily dose of isotretinoin, approximately 1 mg/kg of body weight per day.[16] This high dose induces undesirable side effects, however, and similar short-term therapeutic results are obtained with a dose below 0.5 mg/kg provided the treatment is maintained over a longer period of time.[41] Empirical data from several centers indicate that post-therapy relapse is minimized by administering a cumulative dose of at least 120 mg/kg,[42] and no further therapeutic gain is seen beyond approximately 150 mg/kg.[18] This implies 6 to 8 months of therapy. A lag period of 1 to 3 months may occur before the onset of the therapeutic effect. A flare-up of disease during the first few weeks of treatment and the evolution of acne cysts into lesions resembling pyogenic granuloma may be observed.

Continued healing of acne after the discontinuation of therapy regularly occurs. Approximately one-third of patients with acne require a second course of therapy for either persistent disease or relapse. The only factors predictive of resistance to isotretinoin treatment are the presence of closed comedonal acne and of microcystic acne.[43]

Acitretin and Etretinate

A therapeutic dosage scheme with an initially low dose (10 to 25 mg/day) of acitretin (etretinate requires 20 percent higher dosing because of a higher molecular weight), followed by progressively increasing doses, seems to avoid the increase in the extent of the psoriatic lesions that may occur within a few days of the start of treatment at dosages of 0.5 to 1.0 mg/kg/day (30 to 70 mg/day).[10]

Although the efficacy of a dosage of 10 mg/day was not significantly different from that of the placebo in one study,[10] individual patients may respond to dosages as low as 5 mg/day.

Total clearing of the lesions often requires a combination of treatments, such as retinoids plus topical glucocorticoids, topical vitamin D derivatives, dithranol (anthralin), ultraviolet B irradiation, or photochemotherapy (PUVA treatment).[44–48]

Bexarotene

The recommended initial dosage of bexarotene is 300 mg/m^2/day, administered as a single oral dose with meals. Based on the severity of adverse effects, the dosage may be adjusted down to 100 or 200 mg/m^2/day or administration may be suspended temporarily. If CTCL does not respond after 8 weeks of therapy, the dosage may be increased to 400 mg/m^2/day with careful monitoring.[32,33]

INITIATION AND MONITORING OF THERAPY

Isotretinoin

Women with childbearing potential must have a negative result on a pregnancy test and must practice effective contraception during treatment and for 1 month (2 months in some countries) after the completion of therapy.[49] The SMART (System to Manage Accutane-Related Teratogenicity) and more lately the iPLEDGE program (http://www.ipledgeprogram.com) have been put into effect by the FDA and the manufacturer to minimize the risk of isotretinoin teratogenicity. Similar but less strict programs exist in Europe and elsewhere.

Acitretin and Etretinate

Ensuring that the patient avoids pregnancy during therapy is as imperative when prescribing acitretin and etretinate as when prescribing isotretinoin. However, because of the frequent prospect of long-term treatment of more chronic diseases (e.g., psoriasis and ichthyosis) and the slow elimination of aromatic retinoids from the body after interruption of therapy, acitretin (or etretinate) therapy is usually not recommended for female patients with childbearing potential.

Additional precautions before initiating acitretin therapy include measurement of baseline serum lipid and liver enzyme levels, and anamnestic exclusion of skeletal abnormalities. It is also important to inform the patient beforehand about the possibility of increased hair shedding and other mucocutaneous side effects that will appear during therapy.

Monitoring of serum lipid and liver enzyme levels monthly for the first 2 months and then at 2- to 3-month intervals is adequate in patients with normal baseline levels and absence of risk factors (obesity, high alcohol intake, diabetes).

Bexarotene

The recommendations given for the other retinoids should also be followed for bexarotene, and in addition patients who will receive bexarotene should be screened for thyroid disease. Thyroid hormone and lipid levels in blood should be monitored frequently during therapy.

RISKS AND PRECAUTIONS

Teratogenesis is the most serious adverse effect of oral retinoids. The side effects of systemic retinoids qualitatively resemble hypervitaminosis A syndrome, although important differences exist. The acute retinoid toxicities include mucocutaneous lesions (most patients) and abnormal laboratory test results (less common but may be substantial), whereas the chronic retinoid toxicities involve bony changes (rare).

Teratogenic Effects

Retinoid-induced birth defects include auditory, cardiovascular, craniofacial, ocular, axial and acral skeletal, central nervous system (hydrocephalus, microcephaly), and thymus gland abnormali-

ties.[50] The putative mechanism is toxic effects on neural crest cells, particularly with exposure during the fourth week of gestation.[51]

In men, retinoid therapy does not appear to produce abnormalities in spermatogenesis, sperm morphology, or sperm motility.[52] However, it is usually recommended that men who are actively trying to father children avoid systemic retinoid therapy.

Skin and Mucous Membrane Adverse Effects

Most patients receiving retinoids develop dryness of the lips, skin, and mucous membranes. These dose-related effects reflect mainly decreased sebum production, reduced stratum corneum thickness, and altered skin barrier function. Cheilitis is the earliest and the most frequent sign, followed by blepharoconjunctivitis, dry eyes, dry nose, and dry mouth. Xerosis of the skin, associated with pruritus and peeling, especially of the palms and soles, occurs frequently. Skin fragility and fissuring of fingertips sometimes create a problem, especially for those who work with their hands. Photosensitivity is observed especially with isotretinoin and probably reflects the reduction of thickness of the stratum corneum. Bexarotene appears to induce fewer mucocutaneous and ocular side effects than other classes of retinoids; localized or extensive exfoliative dermatitis is the most common cutaneous side effect with bexarotene.[14] *Staphylococcus aureus* colonization tends to correlate with isotretinoin-induced reduction in sebum production and may lead to overt cutaneous infections.[53] Various ill-defined skin eruptions, called *retinoid dermatitis*, are observed frequently. The erythema is sometimes difficult to differentiate from an underlying psoriasis or atopic dermatitis.

Ocular Adverse Effects

Blepharoconjunctivitis occurs with varying severity in about one-third of patients treated with isotretinoin and may prevent the use of contact lenses. Bacterial conjunctivitis occurs to a lesser extent than *S. aureus* colonization.[54] If artificial tears and topical ophthalmologic antibiotic therapy fail to alleviate the conjunctivitis, ophthalmologic consultation should be sought. Alterations in visual function, mainly poor night vision, excessive glare sensitivity, and changes in color perception, also have been reported.[55]

Hair and Nail Adverse Effects

Diffuse or localized hair loss (telogen effluvium), which is more severe during treatment with acitretin than with isotretinoin, is a common complaint, although objective alopecia tends to occur only at higher dosage levels and after several months of therapy. Nail thinning and paronychia-like changes with periungual granulation tissue may occur.

Musculoskeletal Adverse Effects

Skeletal toxicity was first observed in retinoid-treated patients maintained on a high dosage and after an extended period of continuous treatment for disorders of keratinization. Bone pain without objective evidence of any abnormalities and without sequelae is frequent in retinoid-treated patients. Several reports with conflicting results have implicated synthetic retinoids in the formation of diffuse idiopathic skeletal hyperostosis syndrome–like bone changes and in calcification of tendons and ligaments.[56–58] Prospective studies have shown that the hyperostotic effects of retinoids are mostly asymptomatic and likely involve worsening of pre-existing skeletal overgrowth rather than de novo changes.[59,60] Osteoporosis has been observed with hypervitaminosis A and after long-term therapy with etretinate and to a lesser extent isotretinoin.[61,62] In children, only a few cases of skeletal abnormalities and premature epiphyseal closure[63–65] have been reported. No baseline radiographs are required, although monitoring patients at high risk who receive prolonged high-dose retinoid treatment may be useful.

Muscle pain and cramps rarely occur in patients taking etretinate or acitretin; however, these muscle effects are not infrequent with isotretinoin, particularly in individuals involved in vigorous physical activity (sometimes accompanied by elevations in creatine phosphokinase levels). Increased muscle tone and axial muscle rigidity and myopathy were reported to be related to etretinate and acitretin therapy.[66]

Central Nervous System and Other Neurologic Adverse Effects

Central nervous system side effects are rare. Although individual signs of increased intracranial pressure such as headache, nausea, and vomiting are observed occasionally, the complete syndrome with papilledema (pseudotumor cerebri) and impaired vision is exceptional.[67] Concomitant use by isotretinoin-treated patients of tetracyclines, which rarely produce increased intracranial hypertension, is the major risk factor for development of pseudotumor cerebri.

Anecdotal reports suggest a causal association between isotretinoin therapy and severe depression with suicide attempts.[68] However, large-scale epidemiologic studies provide no evidence that isotretinoin exposure is associated with any greater risk of psychiatric disorders than is antibiotic use in patients with acne.[69]

Pancreatitis

One case of fatal fulminant pancreatitis with acitretin treatment has been reported.[70] Pancreatitis occurred in three patients treated with oral bexarotene, 300 mg/m^2 or more per day, in association with marked elevations of fasting serum triglyceride levels.[32]

Hypothyroidism

Clinical and biochemical central hypothyroidism occurred in 40 percent of patients in the trials of bexarotene therapy for CTCL. It was rapidly and completely reversible with cessation of therapy without any clinical sequelae.[32,71]

Renal Adverse Effects

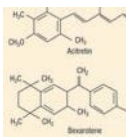
Renal toxicity has not been a characteristic consequence of retinoid administration. Isotretinoin has been administered safely to patients with end-stage kidney disease who were undergoing hemodialysis. However, case reports describing reversible renal function impairment during etretinate therapy advise monitoring of renal function, particularly in patients with a history of renal disorders.[72]

Inflammatory Bowel Disease

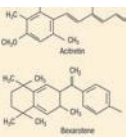
In very rare cases isotretinoin has been linked to exacerbation of inflammatory bowel disease. A 5-year prospective study did not demonstrate an increased risk of inflammatory bowel disease or of cancer, diabetes, or cardiovascular disease in association with long-term etretinate use for psoriasis[70]; similar safety of long-term acitretin or bexarotene therapy has not been established.

Hyperlipidemia

Serum lipid changes are the most frequent abnormalities in laboratory test results



seen with retinoid therapy. Depending on the type and dosage of retinoid, triglyceride levels are elevated in 50 percent to 80 percent and cholesterol levels in 30 percent to 50 percent of treated patients.[32,56,73] Disturbance of blood lipid levels is generally higher with isotretinoin and bexarotene than with acitretin. In cases of severe retinoid-induced hypertriglyceridemia, eruptive xanthomas and acute pancreatitis may occur. Discontinuation of therapy is required if the triglyceride level reaches 800 mg/dL. A less severe increase may be treated by dosage reduction or reduction in alcohol and tobacco consumption. In some instances, use of lipid-lowering agents may be indicated.[74] Co-administration of atorvastatin with bexarotene is recommended.[14] Retinoids probably cause hyperlipidemia by increasing the expression of apolipoprotein-C3, which prevents the uptake of lipids from very-low-density lipoproteins into cells.[75]



Liver Toxicity

Transitory abnormal elevations in serum transaminase levels have been reported in approximately 20 percent of patients treated with etretinate or acitretin and occur much less frequently with isotretinoin and bexarotene. Changes in liver function test results usually occur between 2 and 8 weeks after therapy is begun. Transaminase elevations of more than three times the upper normal range should lead to discontinuation of retinoid therapy.

Severe or persistent hepatotoxic reactions occur in fewer than 1 percent of patients. Acitretin therapy elicited no biopsy-proven hepatotoxicity in a 2-year prospective study.[76] No specific studies have evaluated the use of retinoids in patients with hepatic insufficiency, although this is likely to interfere with drug elimination.

Hematologic Toxicity

A high incidence (28 percent) of dose-related neutropenia has been reported with the use of bexarotene therapy for CTCL, occurring as early as 2 to 4 weeks after initiation of treatment.[32] Hematologic abnormalities are much less common with other retinoids. Bleeding complications due to isotretinoin-induced fibrinolysis has been reported.[77]

COMPLICATIONS

Most adverse effects associated with retinoids are preventable and manageable with proper patient selection, dosage adjustments, discontinuation of treatment, and routine monitoring for potential toxicity. Absolute contraindications are pregnancy or an attempt to become pregnant, non-adherence to a contraceptive regimen, and breast-feeding. Relative contraindications are leukopenia, alcoholism, elevated cholesterol or triglyceride levels, significant hepatic or renal dysfunction, and hypothyroidism (bexarotene).

The concurrent use of retinoids with other therapies having similar side effects may increase the risk of these adverse events. Tetracyclines (increased intracranial pressure, phototoxicity), alcohol (increased conversion of acitretin to etretinate, hepatoxicity), methotrexate (hepatoxicity), and vitamin A supplements (hypervitaminosis A) should be avoided. The concomitant administration of bexarotene and gemfibrozil may result in increased plasma concentrations of bexarotene, at least partially related to CYP 3A4 inhibition by gemfibrozil. In addition, retinoid drug levels may increase with the use of CYP inhibitors such as azoles and macrolides and the CYP competitor cyclosporine, whereas antituberculosis drugs (rifampicin) and anticonvulsants (phenytoin and carbamazepine) actually decrease the drug levels via CYP 3A4 induction.

CHAPTER 230

Antihistamines

Susan L. Limb
Robert A. Wood

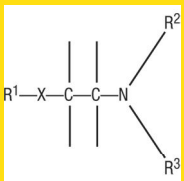
Histamine is a low-molecular-weight amine derived from L-histidine that is produced throughout the body. By means of four known types of receptors, histamine affects cellular growth and proliferation, modulates inflammation, and acts as a neurotransmitter. Both H_1 and H_2 histamine receptors are widely expressed. H_1 receptors are found on neurons, smooth muscle, epithelium and endothelium, and multiple other cell types. H_2 receptors are located in the gastric mucosa parietal cells, smooth muscle, epithelium and endothelium, heart, and other cell types as well. H_3 and H_4 receptors have more limited expression. H_3 receptors are found primarily on histaminergic neurons, whereas H_4 receptors are highly expressed in bone marrow and on peripheral hematopoietic cells.

H_1 ANTIHISTAMINES

Mechanism of Action

H_1 antihistamines are inverse agonists that reversibly bind and stabilize the inactive form of the H_1 receptor, thereby favoring the inactive state[1] (Table 230-1). The backbone structure of H_1 antihistamines is depicted in Fig. 230-1. By means of the H_1 receptor, H_1 antihistamines decrease production of pro-inflammatory cytokines, expression of cell adhesion molecules, and chemotaxis of eosinophils and other cells (Fig. 230-2).[2] H_1 antihistamines may also decrease mediator release from mast cells and basophils through inhibition of calcium ion channels. In addition to having antihistamine actions, first-generation H_1 antihistamines can also act on muscarinic, α-adrenergic, and serotonin receptors and cardiac ion channels. Some of the more serious adverse effects associated with first-generation H_1 antihistamines, such as urinary retention, hy-

ANTIHISTAMINES AT A GLANCE



- H_1 antihistamines are first-line therapy for chronic idiopathic and physical urticarias.
- H_1 antihistamines may be useful in treating other conditions with histamine-driven pruritus.
- Limited evidence supports the use of H_1 antihistamines in treatment of atopic dermatitis.
- Certain special patient populations, including children, the elderly, and patients with renal or hepatic impairment, may require dosage adjustments when using H_1 antihistamines.
- The use of H_1 antihistamines is contraindicated in patients who have narrow-angle glaucoma or who are also taking monoamine oxidase inhibitors.
- H_2 antihistamines may be a useful adjunct to H_1 antihistamine therapy in refractory cases of chronic idiopathic urticaria/angioedema and pruritus.

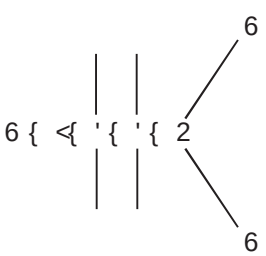
potension, and cardiac arrhythmias, are mediated through these other receptors. The first-generation antihistamines are divided into six groups on the basis of chemical structure: ethylenediamines, ethanolamines, alkylamines, phenothiazines, piperazines, and piperidines[3] (see Fig. 230-1). The presence of multiple aromatic or heterocyclic rings and alkyl substituents enhances the lipophilicity of these compounds, which allows penetration of the blood-brain barrier.

Many of the low-sedating or second-generation H_1 antihistamines are chemically derived from first-generation agents.[2] For example, cetirizine is a metabolite of hydroxyzine. The second-generation H_1 antihistamines bind noncompetitively to the H_1 receptor. They are not easily displaced by histamine, dissociate slowly, and have a longer duration of action than first-generation H_1 antihistamines.[3] Due to the selectivity of second-generation drugs for the H_1 receptor and their reduced lipophilicity, these drugs are far less likely to cause sedation and have different safety profiles than the first-generation drugs.

Some low-sedating H_1-type antihistamines affect the trafficking of cells in the skin and other tissues, presumably by modulating the release of inflammatory mediators and the expression of adhesion molecules. In a skin chamber challenge model, cetirizine administration reduced eosinophil influx after allergen challenge. This effect seems to be specific to cutaneous allergic responses, because similar studies involving nasal challenges have not shown any decrease in eosinophil accumulation in nasal secretions. In vitro, cetirizine inhibits eosinophil, monocyte, and T-lymphocyte chemotaxis in vitro to *N*-formyl-methionyl-leucyl-phenylalanine and platelet-activating factor.[4] H_1 antihistamines may also modulate the expression of cellular adhesion molecules such as antigen-induced intercellular adhesion molecule 1 on keratinocytes, Langerhans cells, and endothelium, and influence the release of inflammatory mediators from leukocytes.[5] Desloratadine and emedastine were found to inhibit platelet-activating factor–induced eosinophil chemotaxis, tumor necrosis factor-α–induced eosinophil adhesion, and spontaneous and phorbol myristate–induced superoxide generation.[6,7]

TABLE 230-1
Basic Pharmacology of Antihistamines

- Both H_1 and H_2 antihistamines are inverse agonists that reversibly bind and stabilize the inactive form of the histamine receptor, thereby favoring the inactive state.
- First-generation H_1 antihistamines are relatively lipophilic, which enhances penetration of the blood-brain barrier and leads to sedation.
- Second-generation, non-sedating H_1 antihistamines bind selectively to peripheral H_1 receptors and have fewer central nervous system effects.
- H_1 antihistamines may interact with other drugs metabolized by the hepatic cytochrome P_{450} system.
- Double-blind, placebo-controlled trials show no evidence of the development of tolerance or tachyphylaxis in the suppression of skin test reactivity by H_1 antihistamines.
- Suppression of skin test reactivity may be observed for up to 7 days after discontinuation of a regularly used sedating H_1 antihistamine.



▲ **FIGURE 230-1** The ethylamine moiety is the backbone structure of most of the first-generation H_1 antihistamines. R = aromatic and/or heterocyclic groups; X = linkage such as nitrogen, oxygen, or carbon.

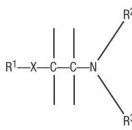
Pharmacokinetics

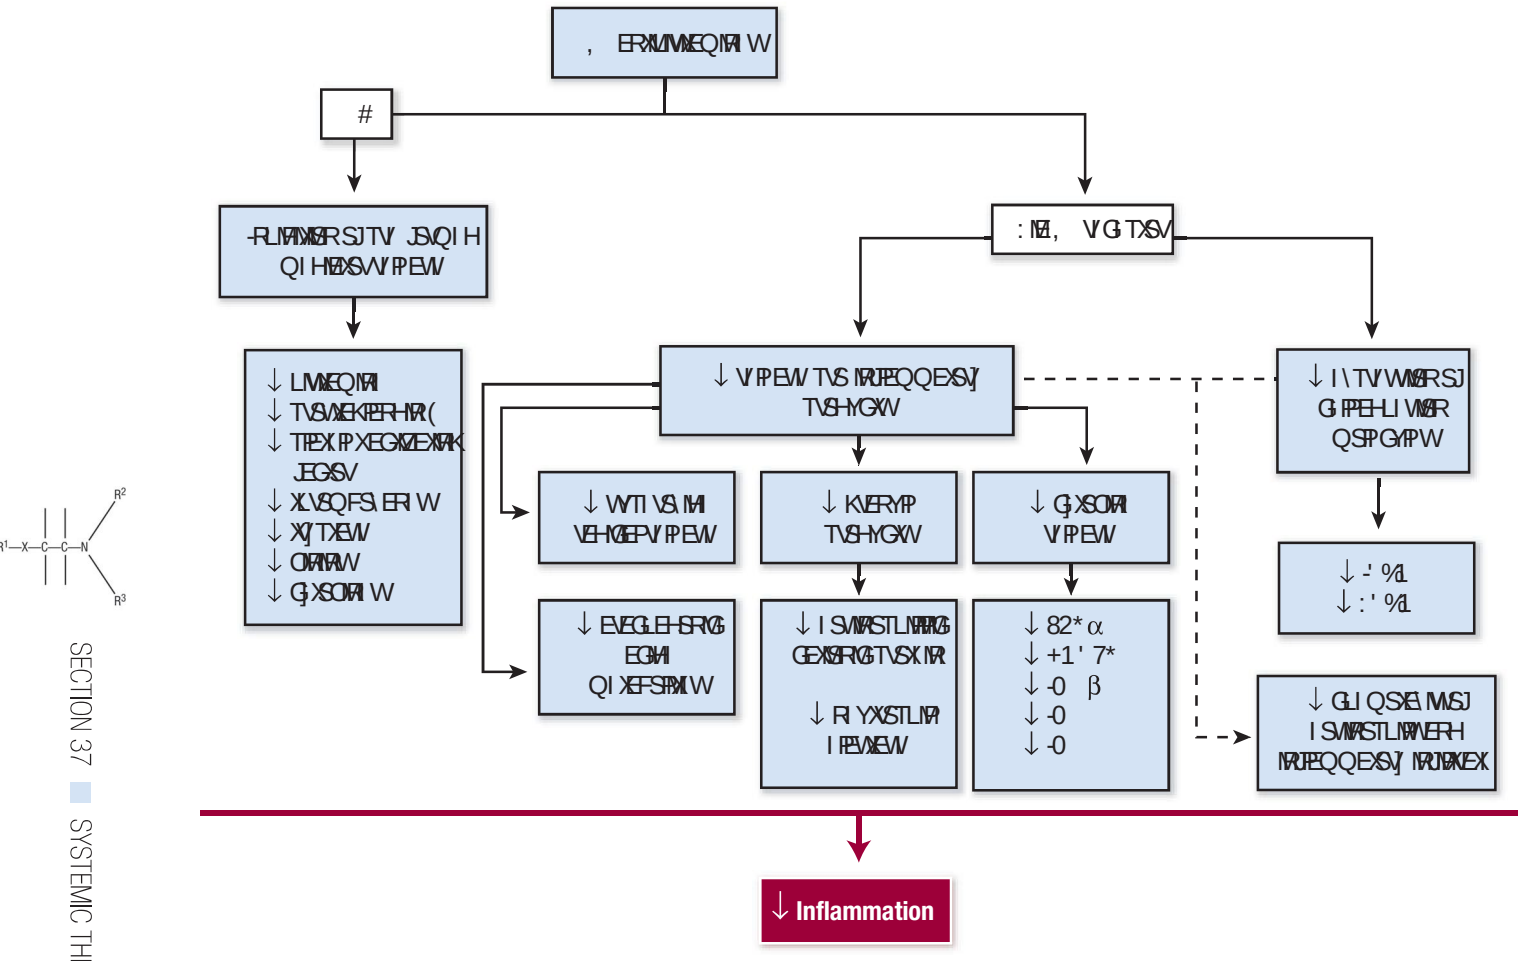
SEDATING, FIRST-GENERATION H_1 ANTIHISTAMINES After oral administration, effects of sedating H_1 antihistamine can be observed within 30 minutes to 1 hour and generally persist for 4 to 6 hours, although the effects of some agents may last for 24 hours and longer.[8] For example, after oral administration of a single dose, the serum half-lives of brompheniramine, chlorpheniramine, and hydroxyzine exceed 20 hours in adults. H_1 antihistamines are metabolized by hepatic cytochrome P_{450} (CYP) enzyme 3A4, forming glucuronides before excretion in urine.

The potency and relative concentration in the skin of H_1 antihistamines can be compared by their inhibition of the cutaneous wheal-and-erythema response to histamine injected cutaneously. In placebo-controlled, double-blind studies, no evidence of tolerance or tachyphylaxis was demonstrated in suppression of skin test reactivity over a 3-month period.[2] Suppression of skin test reactivity may be observed for up to 7 days after discontinuation of a regularly used sedating H_1 antihistamine.

Oral sedating H_1-type antihistamines are typically administered in divided doses at intervals of 4 to 8 hours (see Dosing Regimens), although once-daily dosing may suffice for agents with longer serum half-lives. Topical formulations for dermatologic use are available, although these preparations tend to be less effective and are associated with the development of delayed contact reactions.

LOW-SEDATING, SECOND-GENERATION H_1 ANTIHISTAMINES Most low-sedating, or second-generation, H_1 antihistamines are administered once or twice daily and achieve peak plasma concentrations within two half-lives, although this interval can vary among different drugs and individuals. These drugs generally achieve higher concentrations in the skin than their first-generation counterparts, and a single dose can suppress the wheal-and-erythema reaction from 1 to 24 hours.[9–12] Regular use prolongs this effect; for example, 6 days of daily cetirizine use results in 7 days of suppression of the wheal-and-erythema response.





▲ **FIGURE 230-2** Mode of action of H_1 antihistamines. By means of the H_1 receptor, H_1 antihistamines inhibit the release of pre-formed mediators and decrease the production of pro-inflammatory cytokines, the expression of cell adhesion molecules, and chemotaxis of eosinophils and other cells. ↓ = decreased; GMCSF = granulocyte-macrophage colony-stimulating factor; ICAM-1 = intercellular adhesion molecule 1; IL-1β, IL-6, IL-8 = interleukin-1β, interleukin 6, interleukin 8; TNF-α = tumor necrosis factor-α; VCAM-1 = vascular cellular adhesion molecule 1.

Terfenadine, astemizole, loratadine, acrivastine, mizolastine, ebastine, and oxatomide are metabolized in the liver via the hepatic enzyme CYP 3A4. Cetirizine, fexofenadine, levocabastine, and desloratadine undergo minimal hepatic metabolism, which reduces the likelihood of interactions with other drugs.[8]

In healthy adults, cetirizine reaches peak concentrations around 1 hour after administration, with an elimination half-life of approximately 8 hours.[13] Lower dosages are used in patients with impaired renal or hepatic function. Fexofenadine generally reaches peak concentration at 2 to 3 hours, with an elimination half-life of 14 hours.[13] Dosage adjustment is recommended for patients with decreased creatinine clearance, including the elderly; however, patients with hepatic disease do not require dosage adjustment because fexofenadine undergoes almost no hepatic metabolism.[13] Loratadine's half-life ranges on average from 8 to 24 hours, depending on hepatic function. Ebastine, which is metabolized to form its carboxylic acid metabolite, carebastine, has a half-life of 15 hours.[13] The dosage should be adjusted in patients with impaired renal function. Pharmacogenetics may also influence drug metabolism and clearance. In a series of pharmacokinetic studies, approximately 7 percent of all subjects and 20 percent of African Americans were slow metabolizers of desloratadine.[14] Comparable differences may exist for other H_1 antihistamines.

Indications

H_1 antihistamines are used to treat pruritus of various etiologies, urticaria, and angioedema (Table 230-2). In particular, H_1 antihistamines appear to be effective in treating physical urticarias and dermatographism, in addition to chronic idiopathic urticaria. They are not as effective in treating hereditary and acquired angioedema syndromes and urticarial vasculitis. Few well-controlled, blinded studies of the first-generation H_1-type drugs exist. The general tendency for most chronic urticarias to improve with time and the difficulty in making quantitative assessment of the condition further complicate clinical studies. Comparative studies of the groups of H_1-type antihistamines have shown them to be of equal efficacy.[2] If an agent from one therapeutic group of H_1-type antihistamines proves ineffective, then a trial with an agent from another group may be initiated. In several double-blind, placebo-controlled, or parallel studies, the low-sedating H_1-type antihistamines terfenadine, astemizole, cetirizine, loratadine, fexofenadine, desloratadine, acrivastine,

TABLE 230-2
Indications for Treatment with H_1 Antihistamines

- Acute urticaria
- Chronic idiopathic urticaria
- Physical urticarias and dermatographism
- Atopic dermatitis (less evidence)
- Systemic mastocytosis
- Pruritus associated with other conditions

mizolastine, azelastine, ebastine, and oxatomide were superior to placebo in the treatment of urticaria and angioedema.[15–20] Trials comparing different second-generation antihistamines with one another have not shown any one agent to be consistently superior.[2,15,21]

Both sedating and low-sedating H_1 antihistamines are used to treat pruritus in patients with atopic dermatitis, although their efficacy has not been proved by rigorous clinical trials. In the 18-month Early Treatment of the Atopic Child study, cetirizine afforded a steroid-sparing benefit to children with the most severe atopic dermatitis, but no consistent benefit was observed in children with more moderate disease.[22] A meta-analysis of 16 studies conducted from 1966 through 1999 does not indicate a major role for either first- or second-generation H_1 antihistamines in the treatment of atopic dermatitis, although no randomized, double-blind, placebo-controlled studies are included in this analysis.[23]

H_1 antihistamines are commonly used to treat cutaneous and systemic mastocytosis, although large comparative treatment trials are not available.[24] One early double-blind, placebo-controlled study demonstrated the efficacy of H_1 and H_2 antihistamines in the treatment of systemic mastocytosis.[25] In a later small trial, azelastine compared favorably with chlorpheniramine in the suppression of pruritus in patients with mastocytosis.[26]

Pruritus associated with other conditions, such as allergic contact dermatitis and other forms of eczematous dermatitis, lichen planus, systemic mastocytosis, mosquito bites, infestations, and pruritus secondary to underlying medical disorders or idiopathic pruritus, also may be relieved by H_1 antihistamines, although controlled trials do not exist.[27] In these conditions, the sedative effects of the first-generation agents may be advantageous, permitting more restful sleep. H_1 antihistamines are also used as pre-treatment before certain procedures for patients with a history of radiocontrast media and transfusion reactions.

Dosing Regimens

The dosing regimens for H_1 antihistamines are shown in Table 230-3.

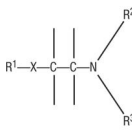


TABLE 230-3
Dosing Regimens for H_1 Antihistamines

Drug	Formulation	Dosage	Conditions Requiring Dosage Adjustment
First-generation H_1 antihistamines			
Chlorpheniramine	2-, 4-, 8-, 12-mg tablet 2 mg/5 mL syrup	Adult: 4 mg tid, qid; 8–12 mg bid Age 6–11 yr: 2 mg q4–6h	Hepatic impairment
Cyproheptadine	4-mg tablet 2 mg/5 mL syrup	Adult: 4 mg tid, qid Age 7–14 yr: 4 mg bid, tid Age 2–6 yr: 2 mg bid, tid	Hepatic impairment
Diphenhydramine	25-, 50-mg tablet 12.5 mg/5 mL syrup 50 mg/15 mL syrup 6.25 mg/5 mL syrup 12.5 mg/5 mL syrup	Adult: 25–50 mg q4–6h Age 6–12 yr: 12.5–25 mg q4–6h Age < 6 yr: 6.25–12.5 mg q4–6h	Hepatic impairment
Hydroxyzine	10-, 25-, 50-, 100-mg tablet 10 mg/5 mL syrup	Age ≥ 6 yr: 25–50 mg q6–8h or qhs Age < 6 yr: 25–50 mg qd	Hepatic impairment
Tripelennamine	25-, 50-, 100-mg tablets	Adult: 25–50 mg q4–6h	Hepatic impairment
Second-generation H_1 antihistamines			
Acrivastine[a]	8-mg tablet	Adult: 8 mg tid	Renal impairment
Azelastine	2-mg tablet[b] 0.1% nasal spray	Adult: 2–4 mg bid Age 6–12 yr: 1–2 mg bid 2 sprays/nostril bid	Renal and hepatic impairment
Cetirizine	5-, 10-mg tablet 5 mg/mL syrup	Age ≥ 6 yr: 5–10 mg qd Age 2–6 yr: 5 mg qd Age 6 mo–2 yr: 2.5 mg qd	Renal and hepatic impairment
Desloratadine	2.5-, 5-mg tablet 5 mg/mL syrup	Age ≥ 12 yr: 5 mg qd Age 6–12 yr: 2.5 mg qd Age 1–6 yr: 1.25 mg qd Age 6–12 mo: 1 mg qd	Renal and hepatic impairment
Ebastine[b]	10-mg tablet	Age ≥ 6 yr: 10–20 mg qd Age 6–12 yr: 5 mg qd Age 2–5 yr: 2.5 mg qd	Renal impairment
Fexofenadine	30-, 60-, 120-, 180-mg tablet	Age ≥ 12 yr: 60 mg qd, bid; 120–180 mg qd Age 6–12 yr: 30 mg qd, bid	Renal impairment
Levocetirizine[b]	5-mg tablet	Age ≥ 6 yr: 5 mg qd	Renal and hepatic impairment
Loratadine	10-mg tablet 5 mg/mL suspension	Age ≥ 6 yr: 10 mg qd Age 2–9 yr: 5 mg qd	Renal and hepatic impairment
Mizolastine[b]	10-mg tablet	Adult: 10 mg qd	Hepatic impairment

[a]Available in the United States only as a fixed-dose combination with pseudoephedrine hydrochloride, 120 mg.
[b]Not currently available in the United States.
Data from refs. 2, 3, 8, 13, 14, 28.

Initiation of Therapy

The H_1 antihistamines are considered first-line therapy in the treatment of chronic idiopathic and physical urticarias and may be useful in treating other conditions in which histamine-driven pruritus is a major feature. The lowest effective dosage is preferred to minimize dose-related side effects, such as sedation. After several days of therapy, the dosage may be increased and titrated. Occasionally, gradual escalation of dosing permits the development of tolerance to sedation, which allows higher dosages to be used to treat certain conditions, such as refractory chronic urticaria. Ingestion of the medication with food may alleviate any gastrointestinal discomfort, although patients should be advised to avoid taking fexofenadine with antacids, which can interfere with drug absorption. Individuals with co-morbid conditions, such as renal or hepatic disease, may require lower dosages due to impaired metabolism of these drugs. Certain special patient populations, including children, the elderly, and pregnant or breast-feeding women, may also need dosage adjustments (see Special Patient Populations). Some situations may call for more careful assessment of H_1 antihistamine therapy[2] (Table 230-4).

Monitoring of Therapy

Therapeutic endpoints are evaluated by observation of clinical signs and symptoms (e.g., severity of pruritus; wheal number, size, and frequency). As for drug toxicity, no particular monitoring beyond the usual surveillance for adverse effects is required in most cases. Certain individuals, such as patients with impaired metabolism or other co-morbid conditions and those taking other medications, may require closer monitoring and counseling regarding the use of H_1 antihistamines. Because of reports of hepatotoxicity, some sources recommend periodic liver transaminase evaluation when cyproheptadine is used.[28]

TABLE 230-4
Factors for Risk-Benefit Assessment of H_1 Antihistamine Therapy

- Risks
  - History of cardiac arrhythmias, particularly ventricular arrhythmias
  - First trimester of pregnancy
  - Prostatic hypertrophy
- Contraindications
  - Narrow-angle glaucoma
  - Concomitant use of monoamine oxidase inhibitors

Risks and Precautions

Adverse effects are listed in Table 230-5. Sedation is the most commonly reported problem, primarily with first-generation H_1 antihistamines.[2,3,8] The sedative effect is more pronounced with the ethanolamine and phenothiazine groups and is less marked with the alkylamine group. The sedative effect may diminish after a few days of continual use of H_1-type antihistamines. If tolerance to sedation does not occur, an agent from another group should be tried. The use of H_1-type antihistamines has been associated with an increase in occupational injuries and automobile accidents.[29] Other central nervous system (CNS) effects include dizziness, tinnitus, disturbed coordination, inability to concentrate, blurred vision, and diplopia. Stimulatory CNS effects, which occur especially with the alkylamine group, include nervousness, irritability, insomnia, and tremor.

Gastrointestinal complaints, including anorexia, nausea, vomiting, epigastric distress, diarrhea, and constipation, are another frequent side effect, especially with the ethylenediamine group.[3] The administration of these agents with food may reduce these manifestations.

Anticholinergic effects include dry mucous membranes, urinary retention and hesitancy, postural hypotension, dizziness, erectile dysfunction, and constipation.[2] These effects are often associated with the ethanolamine, phenothiazine, and piperazine groups. The anticholinergic effects of H_1-type antihistamines preclude their use in patients with narrow-angle glaucoma and require close monitoring in patients with prostatic hypertrophy (see Table 230-4).

Arrhythmias, particularly prolongation of the QT interval and torsades de pointes, are the most serious cardiac toxicity.[2,3] These dose-dependent effects are mediated through blockade of potassium channels unrelated to the H_1 histamine receptor. Transient hypotension may develop after intravenous therapy, especially if the drug is administered rapidly.[30]

The occurrence of cutaneous reactions after the administration of oral H_1-type antihistamines is uncommon. Reported reactions include eczematous dermatitis, allergic contact dermatitis, urticaria, petechiae, fixed drug eruptions, and photosensitivity. Some of these reactions may be secondary to excipients in the drug.

TABLE 230-5
Adverse Effects of H_1 Antihistamines

- Sedation (primarily first-generation agents)
- Other central nervous system disturbances
  - Dizziness
  - Tinnitus
  - Blurred vision
  - Irritability or nervousness
  - Insomnia
  - Tremor
- Gastrointestinal complaints
  - Nausea and vomiting
  - Diarrhea or constipation
  - Anorexia
- Anticholinergic effects
  - Dry mucous membranes
  - Urinary retention
  - Postural hypotension
- Cardiac arrhythmias (particularly prolongation of the QT interval, ventricular arrhythmias, torsades de pointes)
- Hypersensitivity reactions (rare)

Due to the selectivity of the low-sedating H_1 antihistamines for peripheral H_1 receptors, these drugs lack both the sedative and anticholinergic side effects commonly associated with the first-generation drugs.[31] For the second-generation drugs, sedation is most often reported in a subset of patients taking cetirizine and acrivastine. Although far less sedating than its parent compound hydroxyzine, cetirizine causes sedation in approximately 10 percent to 15 percent of users.[32] This effect appears to be dose dependent and can often be mitigated by dosing adjustment.[33] Fifteen percent to 35 percent of patients report somnolence secondary to acrivastine use.[34] In contrast, fexofenadine, loratadine, and desloratadine cause negligible sedation.[35]

Two early second-generation H_1 antihistamines, terfenadine and astemizole, have been removed from U.S. market due to risk of QT interval prolongation and torsade de pointes. Other second-generation agents have an approximately 1000-fold lower affinity for cardiac ion channels, and ventricular arrhythmias have not been associated with later second-generation agents.[2] A theoretical risk remains, however, and may be a consideration before initiating therapy in patients susceptible to tachyarrhythmias.

Drug Interactions

The H_1 antihistamines may interact with other drugs metabolized by the

hepatic CYP system, such as imidazole antifungals, cimetidine, and macrolide antibiotics.[3] Diphenhydramine, chlorpheniramine, clemastine, promethazine, hydroxyzine, and tripelennamine inhibit the hepatic enzyme CYP 2D6 in vitro.[36] In vivo, diphenhydramine has been noted to increase levels of other drugs metabolized by the CYP 2D6 system, including metoprolol and venlafaxine.[37,38] H_1-type antihistamines are contraindicated for patients receiving monoamine oxidase inhibitors.

Central depressive effects may be accentuated when H_1-type antihistamines are combined with alcohol or other CNS depressants, such as benzodiazepines. These interactions are generally not observed with second-generation H_1 antihistamines.[3]

In rare circumstances, antihistamines of the phenothiazine group may block and reverse the vasopressor effect of epinephrine. If individuals receiving a phenothiazine require a vasopressor agent, norepinephrine or phenylephrine should be used.

Special Patient Populations

CHILDREN Many of the sedating and low-sedating H_1 antihistamines can be safely used in children with appropriate dosing. Children may be more susceptible to certain side effects associated with first-generation drugs, such as excitation and insomnia. Acute poisoning may develop but is rare; hallucinations, ataxia, incoordination, athetosis, and convulsions are the major features.

ELDERLY Caution should be used when treating elderly patients, and decreased creatinine clearance, co-morbid conditions, and potential drug interactions should be taken into account. Older individuals may also be more susceptible to anticholinergic effects, particularly urinary retention and hesitancy, constipation, and postural hypotension.[3]

PREGNANT WOMEN There are limited guidelines for the use of H_1 antihistamines to treat pregnant women. Most H_1 antihistamines are classified as U.S. Food and Drug Administration (FDA) pregnancy category B or category C. Based on earlier reports linking H_1 antihistamines to fetal malformations, particularly cleft palate defects, H_1 antihistamines are customarily avoided in the first trimester of pregnancy.[39] However, more recent studies, including a meta-analysis of 200,000 first-trimester exposures to first-generation antihistamines, do not indicate any increased risk of congenital malformations associated with H_1 antihistamine use.[40] In a prospective trial, astemizole administered to pregnant women was not associated with intrauterine growth retardation or perinatal complications.[41] The rate of birth malformations was identical to that in the control group and to that in the general population.

BREAST-FEEDING WOMEN No formal studies have been performed on the safety of H_1 antihistamines during breast-feeding. Theoretically, first-generation drugs may diminish milk supply via anticholinergic effects. Clemastine, diphenhydramine, promethazine, triprolidine, cetirizine, loratadine, fexofenadine, and desloratadine are all known to be excreted in breast milk; their effects on the nursing infant are not known.[3]

H_2 ANTIHISTAMINES

Mechanism of Action

Similar to their H_1-binding counterparts, H_2 antihistamines are inverse agonists that bind H_2 receptors located throughout the body, including epithelial and endothelial cells. More recently, there is evidence that H_2 receptors are expressed on mast cells and dermal dendritic cells as well. Through binding of these receptors, H_2 antihistamines may mediate cutaneous vascular permeability, local release of inflammatory mediators and cellular recruitment, and antigen presentation, but these pathways remain poorly understood, and their clinical significance is unknown.

Pharmacokinetics

H_2-type antihistamines are rapidly absorbed from the gastrointestinal tract with peak levels occurring between 1 and 2 hours after administration. They undergo extensive hepatic metabolism with renal clearance. Only a small proportion of cimetidine is absorbed from the stomach; most of its absorption occurs in the small intestine. The half-life of cimetidine in plasma is 2 hours. Approximately 69 percent is excreted unchanged in the urine.[42] The plasma half-life of ranitidine is 2 to 3 hours in healthy adults, longer in individuals with liver or kidney disease and in the elderly.[43] The drug and its metabolites are excreted principally in the urine. Famotidine has a plasma half-life of 3 to 8 hours. In patients with renal failure, the half-life of famotidine may exceed 20 hours.[44] Nizatidine has a plasma half-life of 1 to 2 hours, and its duration of action is up to 10 hours.[45] Nizatidine is primarily eliminated by the kidneys within 16 hours. The oral bioavailability of nizatidine is not affected by food. These agents are relatively lipophilic with limited penetration of the blood-brain barrier.

TABLE 230-6
Dermatologic Indications for Treatment with H_2 Antihistamines

- Acute allergic reactions
- Chronic urticaria
- Urticaria pigmentosa and systemic mastocytosis
- Pruritus associated with other conditions

Indications in Dermatology

There are few data from controlled studies supporting the use of H_2 blockers to treat dermatologic conditions (Table 230-6). Most often, these agents are used in addition to H_1 antihistamines in refractory cases of chronic urticaria and angioedema. In a double-blind crossover study, greater reductions in pruritus and wheal number, size, and severity were observed with the combination of hydroxyzine and cimetidine than with hydroxyzine alone.[46] Similar observations have been made for chlorpheniramine combined with cimetidine.[47] Combination H_1 and H_2 antihistamine therapy may also be helpful in reducing the pruritus and whealing associated with systemic mastocytosis and urticaria pigmentosa. A double-blind crossover trial of chlorpheniramine and cimetidine suggested that the combination was effective in reducing the pruritus and whealing.[25]

There are anecdotal reports of the use of cimetidine to treat pruritus secondary to various medical conditions such as polycythemia vera[48] and carcinoid flush.[49] High doses of cimetidine were successful in the treatment of verruca vulgaris in some individuals.[50]

Dosing Regimens

The dosing regimens for H_2 antihistamines are given in Table 230-7.

Initiation of Therapy

For treatment of dermatologic conditions, H_2 antihistamines are generally used in conjunction with H_1 antihistamines, usually following an unsuccessful trial of H_1

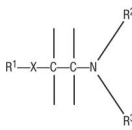

TABLE 230-7
Dosing Regimens for H_2 Antihistamines

Drug	Formulation	Dosage	Conditions Requiring Dosage Adjustment
Cimetidine	100-, 200-, 300-, 400-, 800-mg tablet 300 mg/5 mL syrup 200 mg/20 mL syrup	Adult: 400–800 mg bid	Renal or hepatic impairment
Ranitidine	75-, 150-, 300-mg tablet 15 mg/mL syrup 150-mg granules	Adult: 75–150 mg bid Pediatric: 5–10 mg/kg/day divided in 2 doses	Renal impairment
Famotidine	10-, 20-, 40-mg tablet 40 mg/5 mL syrup	Adult: 20–40 mg bid Age 1–16 yr: 1 mg/kg/day divided in 2 doses, up to 40 mg bid	Renal impairment
Nizatidine	150-, 300-mg capsule 15 mg/5 mL syrup	Age ≥ 12 yr: 150 mg qd, bid	Renal impairment

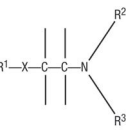
TABLE 230-8
Adverse Effects of H_2 Antihistamines

- Central nervous system disturbances
  - Confusion
  - Headache
  - Dizziness
  - Drowsiness
- Gastrointestinal effects
  - Nausea or vomiting
  - Diarrhea or constipation
  - Abdominal pain
  - Increased transaminases and hepatitis (rare)
- Gynecomastia
- Increased susceptibility to pneumonia
- Hematologic (rare)
  - Thrombocytopenia
  - Anemia
- Hypersensitivity to H_2 antihistamines (uncommon)
- Drug interactions
- Cardiac effects (with concomitant administration of dofetilide; dofetilide use is therefore a contraindication)



antihistamines alone. In most cases, treatment with H_2 antihistamines may be initiated without any particular laboratory screening. The inhibition of the hepatic CYP system and the potential for drug interactions is usually the greatest concern, and patients' medication lists should be reviewed carefully before initiating therapy. Ranitidine is less inhibitory of the CYP system than cimetidine and may be the preferred H_2 antihistamine in situations in which drug interactions are a particular concern.[43] Patients with decreased creatinine clearance require dosage adjustment.[51] In patients taking the cardiac drug dofetilide, cimetidine is absolutely contraindicated because of the risk of prolongation of the QT interval and life-threatening cardiac arrhythmias.[52]

Monitoring of Therapy

Therapeutic endpoints are evaluated by observation of clinical signs and symptoms (e.g., severity of pruritus; wheal size, frequency, and intensity). As far as drug toxicity is concerned, no particular monitoring beyond the usual surveillance for adverse effects is required in most cases. For patients with a history of thrombocytopenia, a complete blood count may be warranted once H_2 antihistamine therapy is initiated, because thrombocytopenia has been reported as an idiosyncratic effect of these drugs in a few individuals.[53]

Risks and Precautions

H_2 antihistamines may have several CNS effects, including confusion, headache, and dizziness[54] (Table 230-8). These effects seem to be partly dose related. Other side effects include drowsiness, malaise, muscular pain, diarrhea, and constipation. There are rare reports of granulocytopenia. By their suppression of gastric acid secretion, H_2 antihistamines may facilitate oral infections and increase the risk of pneumonia in immunocompromised individuals, including diabetic patients, the elderly, and patients with immunodeficiency.[55] As a class, these drugs may mask symptoms of gastric carcinoma. Cimetidine and ranitidine both inhibit alcohol dehydrogenase activity, which leads to increased blood alcohol levels.

Uncommon side effects of cimetidine include gynecomastia with or without elevated prolactin levels in men; galactorrhea with elevated prolactin levels in women; and loss of libido, impotence, and reduction of sperm counts in young men.[42,56] Modest elevations in serum creatinine levels and hepatic transaminase levels have both been reported and are reversible after the drug is withdrawn.[43,56] Rare dermatologic adverse effects, including alopecia and urticarial vasculitis, have also been reported.[57]

Ranitidine does not bind to androgen receptors and does not enhance cell-mediated immune responses.[43] Ranitidine may affect physiologic autonomic control of the cardiovascular system by altering parasympathetic and sympathetic control functions.[58] This altered cardiac sympathovagal balance may lead to a susceptibility to arrhythmias, particularly bradyarrhythmias, after intravenous infusion.

Famotidine and nizatidine are associated with few side effects; they also cause less inhibition of the CYP system and therefore are involved in fewer drug interactions.[44,45]

Drug Interactions

Through inhibition of the CYP system, cimetidine increases the serum levels of numerous drugs, including some of the most common medications used in the care of the medical patient.[56] Of note, cimetidine increases levels of warfarin and may cause dangerous increases in prothrombin time and risk of bleeding. Cimetidine also interacts with many cardiac drugs—several β blockers, calcium channel blockers, amiodarone, antiarrhythmic agents, among others. As already mentioned (see Initiation of Therapy), cimetidine use is contraindicated in patients taking dofetilide. Other common drugs with which cimetidine interacts are phenytoin, several benzodiazepines, metformin, sulfonylureas, and selective serotonin reuptake inhibitors.

Although ranitidine interacts with other medications less frequently than does cimetidine, significant interactions with fentanyl, metoprolol, midazolam, nifedipine, theophylline, and warfarin have been observed.[43] Ranitidine may decrease the absorption of diazepam and reduce its plasma concentration by 25 percent. Famotidine and nizatidine are associated with fewer drug interactions.

Special Patient Populations

CHILDREN Of the H_2 antihistamines, ranitidine and famotidine have pharmacokinetics that have been relatively well

studied in children, and these drugs have acceptable safety profiles with appropriate dosing. Cimetidine and nizatidine are not recommended for children. One adverse effect unique to children is an uncommon but drug class–wide risk of necrotizing enterocolitis in neonates.[59]

ELDERLY Older patients may require downward adjustment of dosage to accommodate decreased creatinine clearance, as well as careful review of medication lists. Elderly patients also appear more susceptible to CNS disturbances such as confusion and dizziness.

PREGNANT WOMEN The H_2 antihistamines are classified as FDA pregnancy category B drugs. Cimetidine, ranitidine, famotidine, and nizatidine are all excreted in breast milk; potential effects on the nursing infant have not been studied.[43–45,56]

OTHER THERAPEUTIC AGENTS WITH ANTIHISTAMINIC ACTIVITY

Tricyclic Antidepressants

Tricyclic antidepressants bind both H_1 and H_2 receptors. The tricyclic antidepressant most commonly used in dermatology is doxepin. Oral doxepin has been used successfully in the treatment of refractory chronic idiopathic urticaria, physical urticaria, and pruritus associated with systemic conditions.[60,61] In a double-blind, crossover study (n = 50), doxepin proved more efficacious than diphenhydramine in the treatment of chronic idiopathic urticaria.[62] Topical preparations are also available. In double-blind, vehicle-controlled trials, topical doxepin cream reduced pruritus in patients with atopic dermatitis and lichen simplex chronicus.[63]

Sedation is the most common adverse effect with both the oral form and the topical form, which is absorbed percutaneously, although some patients may develop tolerance with regular use. Oral doxepin has been classified by the FDA as a pregnancy category C drug; topical doxepin is classified as a pregnancy category B drug.[64] Use of both oral and topical forms is contraindicated during breast-feeding. The safety and efficacy of doxepin therapy in children under the age of 12 has not been established. The drug should be used with caution in elderly patients, who may be more susceptible to its anticholinergic effects, including urinary retention and blurred vision.[60] Doxepin should not be used concurrently with monoamine oxidase inhibitors, and all patients with underlying depression should be closely monitored for signs of suicidal ideation when initiating drug therapy. Doxepin may also cause a sudden increase in intraocular pressure and should not be used in patients with glaucoma.

Ketotifen

Ketotifen, a benzocycloheptathiophene derivative, is an H_1-type antihistamine with additional mast cell– and basophil-stabilizing properties.[1] Ketotifen has been used successfully in the treatment of chronic idiopathic urticaria, physical urticaria, and urticaria pigmentosa.[65–67] In a double-blind trial involving 305 patients with chronic idiopathic urticaria ketotifen alleviated pruritus more effectively than clemastine or placebo.[68] More recent studies comparing ketotifen with low-sedating H_1 antihistamines are not available. Results of one early open-label trial suggested that ketotifen not only reduces the pruritus and pain of neurofibromatosis but also slows the growth of neurofibromas[69]; however, these results have not been confirmed by other investigators. Sedation and atropine-like effects are common.[70] There are no studies evaluating the safety of ketotifen in pregnant or breast-feeding women. Ketotifen is available in the United States only as an ophthalmic solution.

Mirtazapine

Mirtazapine is a tetracyclic antidepressant with H_1 antihistamine properties.[61] Several case series have reported its successful use in reducing pruritus attributable to uremia, cholestasis, and various cancers, but it has not been well studied as a primary dermatologic agent. Patients taking mirtazapine require monitoring of blood counts and lipid levels for hyperlipidemia and the rare but serious adverse effects of agranulocytosis and neutropenia. Mirtazapine carries an FDA black box warning of possible increased risk of suicide, particularly during initiation of therapy, and its concomitant use with monoamine oxidase inhibitors is contraindicated. It is classified as an FDA pregnancy category C drug, and its safety during breast-feeding and in children has not been established.

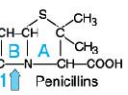
CHAPTER 231

Antibiotics

Christopher C. Gasbarre
Steven K. Schmitt
Kenneth J. Tomecki



Antibiotics are soluble compounds produced by an organism that inhibit bacterial growth; the term also includes synthetic compounds such as fluoroquinolones. The majority of skin and soft-tissue infections (SSTIs) are caused by Gram-positive organisms, most of which are susceptible to well-known agents with a relatively narrow spectrum of antimicrobial activity, and β-lactams, macrolides, and fluoroquinolones have been the mainstays of therapy.[1] Increased use and misuse of these antibiotics has led to selection and propagation of resistant bacteria. Community-acquired resistant pathogens, such as methicillin-resistant *Staphylococcus aureus* (MRSA), have recently emerged as causes of some SSTIs, including cellulitis, folliculitis, furunculosis, impetigo, erysipelas, and abscesses. More ominous is the emergence of complicated SSTIs caused by resistant pathogens (e.g., MRSA and vancomycin-resistant enterococci). Complicated cutaneous infections include those involving deeper tissues, those requiring surgical intervention, and those coincidental with underlying diseases that may complicate therapy. Combination therapy with well-established antimicrobials has been effective in many cases, and new antibiotics have broadened treatment options. However, given the relative paucity of new antimicrobials on the horizon, dermatologists are likely to be faced with growing treatment challenges. Understanding the pharmacologic properties of antibiotics ensures the most judicious use of these agents, and familiarity with antibiotic dosing schedules and adverse events will lead to therapeutic choices that achieve the highest degree of patient adherence to the treatment regimen.

BASIC PRINCIPLES

Mechanism of Action

Antibiotics are largely classified by their chemical structures and related mechanisms of action. Four major groups exist: (1) Some antibiotics inhibit the formation of bacterial cell walls, such as the β-lactams (penicillins, cephalosporins, and carbapenems) and vancomycin. These agents are generally bactericidal. (2) Some antibiotics interfere with protein synthesis by binding to either the 50S or 30S bacterial ribosomal subunit and may be bacteriostatic or bactericidal. Reversible binding (tetracyclines, macrolides, lincosamides, and linezolid) usually halts microbial growth, resulting in a bacteriostatic effect. Irreversible bactericidal binding occurs with aminoglycosides. (3) Some agents interfere with bacterial nucleic acid synthesis, such as rifampin (inhibits RNA polymerase) and quinolones (inhibit bacterial topoisomerase). These agents are typically bactericidal. (4) Some antibiotics interfere with key enzymes in folate metabolism, such as trimethoprim and sulfonamides.

Bacteriocidal versus Bacteriostatic Agents

Although antibiotics may be considered bactericidal (producing cell death) or bacteriostatic (halting cell growth or division), the distinction is based on in vitro assays. In an immunocompetent host, both modes of action can eliminate pathogens. Other considerations, such as absorption, tissue distribution, and drug metabolism and elimination, often play a more important role in eradication of infection. In addition, some antibiotics are variably bacteriotoxic and bacteriostatic, depending on the infective organism. There are a few situations in which the distinction may be clinically relevant: bacterial meningitis, infective endocarditis, osteomyelitis, and infections occurring in neutropenic patients. Finally, host factors such as immunocompromising disease or therapy and the ability to debulk infections by débridement or drainage may also overshadow in vitro susceptibility in treating infection.

Susceptibility Testing

Susceptibility testing, after isolation and identification of an organism from an appropriate clinical specimen, helps to direct therapy.

Resistance Mechanisms

Since the advent of antibiotics, microbes have become increasingly resistant to available therapies. Approximately 70 percent of all infective bacteria encountered in the hospital setting have developed resistance to at least one of the antibiotics initially used to treat them. For an antibiotic to be effective, it must reach its target in an active form, bind to the target, and inhibit the organism's growth. Bacteria can evade the intended action if one of the following occurs: (1) The drug cannot reach its target (e.g., efflux pumps in the bacterial cell membrane can remove antibiotics from the cell). Numerous antibiotics (β-lactams, tetracyclines, fluoroquinolones, and macrolides) are eliminated in this fashion. (2) The drug is inactivated, as exemplified by resistance to β-lactams by organisms able to produce β-lactamase. (3) The drug can no longer bind its target. Numerous permutations of this mechanism are known. One example is the natural mutation of bacterial topoisomerases, which results in fluoroquinolone resistance.

Pharmacokinetics and Pharmacodynamics

Pharmacokinetics refers to the absorption, distribution, and elimination of a drug.[2] Peak and trough serum concentrations after antimicrobial dosing are examples of pharmacokinetic parameters.

ANTIBIOTICS AT A GLANCE

- The β-lactam antibiotics (penicillins and cephalosporins) are mainstays of therapy for the treatment of uncomplicated skin and soft-tissue infections (SSTIs).
- Empiric therapy for uncomplicated SSTIs is largely successful.
- Antibiotic resistance is a growing concern. Culture and sensitivity testing may allow for better management of infections caused by resistant organisms.
- The β-lactam antibiotics and vancomycin act by inhibiting bacterial cell wall synthesis.
- Several antibiotic classes interfere with bacterial protein synthesis by binding ribosomal subunits: Tetracyclines at 30S and lincosamides (clindamycin), macrolides, streptogramins, and oxazolidinones (linezolid) at 50S.
- New agents approved for the treatment of SSTIs include linezolid, quinupristin/dalfopristin, daptomycin, ertapenem, and tigecycline.

Adjustments for Renal Insufficiency

Many antibiotics excreted by the kidneys require dosing adjustments for patients with renal insufficiency to ensure adequate dosing and avoid drug toxicity (Table 231-1). Adjustments to either the amount of drug or the frequency of its administration are based on creatinine clearance (C_{CR}), which is most easily approximated using the following calculation:

$$C_{CR} = \frac{\text{ideal weight (kg)} \times (140 - \text{age})}{72 \times \text{serum creatinine level (mg/dL)}}$$

This formula applies to men; for women, the result is multiplied by 0.85. Some antibiotics are removed by hemodialysis and require higher dosing.

Use during Pregnancy and Lactation

Ideally, systemic antibiotics should be avoided during pregnancy. However, for the treatment of uncomplicated SSTIs, penicillins, cephalosporins, and erythromycin, which are U.S. Food and Drug administration category B medications, are considered the safest candidates for use. As category D medications, tetracyclines, fluoroquinolones, and trimethoprim-sulfamethoxazole are contraindicated during pregnancy (Table 231-2). Most antibiotics are considered safe for lactating (breast-feeding) women, but fluoroquinolones should be avoided due to possible development of arthropathies and cartilage defects.[3] Metronidazole, infrequently used systemically in dermatologic practice, has carcinogenic and mutagenic risk. If it is used, current guidelines recommend discontinuation of breast-feeding for 12 to 24 hours to allow for excretion of the drug.

Prophylaxis and Perioperative Use

The prophylactic use of antibiotics in dermatology and dermatologic surgery is controversial.[4,5] Published guidelines and existing studies regarding prophylaxis inadequately address dermatologic procedures (such as prolonged procedures and involvement of mucosal sites), and a current consensus does not exist. It is likely that antibiotics are currently overused in this setting, and several publications have now proposed guidelines relevant to dermatology. Prophylactic antibiotic use may be considered for two purposes: (1) prevention of endocarditis and prosthesis infection, and (2) prevention of surgical site infection.

The American Heart Association published its most recent guidelines regarding endocarditis prophylaxis in 1997. Patients are risk-stratified by underlying condition. Antibiotic prophylaxis is recommended for patients with high-risk conditions who are undergoing procedures in which the risk of bacteremia exceeds 10 percent. High-risk conditions include the presence of prosthetic cardiac valves, history of previous bacterial endocarditis, complex cyanotic congenital heart disease, and the presence of surgically constructed pulmonary shunts. Several studies have demonstrated that bacteremia rates for routine dermatologic surgical procedures involving properly cleansed and noninflamed skin are close to 3 percent. In comparison, toothbrushing produces bacteremia rates of between 24 percent and 40 percent. Therefore, antibiotic use for prophylaxis against endocarditis is not indicated for routine surgical procedures on noninflamed and surgically prepared skin. The data for procedures

TABLE 231-1
Dosing Regimens for Antibiotics Commonly Prescribed for the Treatment of Skin and Soft-Tissue Infections

Class	Generic Name	Route	Adult Dosing
β-Lactams	Penicillin G	IM, IV	2–24 million units qd divided q4h[a] (18–24 million units qd for neurosyphilis)
	Benzathine penicillin G	IM	2.4 million units × 1 (early syphilis)[a] 2.4 million units weekly × 3 (syphilis > 1 yr)
	Dicloxacillin	PO	500 mg q6h
	Nafcillin	IM, IV	IM: 500 mg q4–6h IV: 0.5–2 g q4–6h
	Oxacillin	IM, IV	1–2 g q4–6h
	Amoxicillin	PO	500 mg q8h[a]
	Amoxicillin/clavulanate	PO	875 mg q12h[a]
	Cephalexin[d]	PO	500 mg q6h
	Cefdinir[e]	PO	300 mg q12h
	Cefprozil[f]	PO	250 mg q12h
Tetracyclines	Tetracycline	PO	500 mg q6h (bid for acne)[a]
	Doxycycline	PO	100 mg q12–24h[a]
	Minocycline	PO	100 mg q12h[a]
Macrolides	Erythromycin base	PO	500 mg q6h or q12h
		IV	1 g q6h[a]
	Clarithromycin	PO	250–500 mg q12h
	Azithromycin	PO	500 mg on day 1, then 250 mg qd × 2–5 Chlamydia: 1 g single dose
		IV	500 mg q24h
Fluoroquinolones	Ciprofloxacin	PO, IV	Gonorrhea: 500 mg × 1[b] Gonococcemia: 500 mg q12h × 7 days[c] Chancroid: 500 mg q12h × 3 days Cutaneous anthrax: 10–15 mg/kg q12h × 60 days
	Levofloxacin	PO, IV	Uncomplicated infection: 500 mg q24h[a] Complicated infection: 750 mg q24h[a]
Lincosamides	Clindamycin	PO	150–450 mg q6h
		IV	600–900 mg q8h
Trimethoprim-sulfamethoxazole (co-trimoxazole)		PO	180 mg/800 mg (double strength) q12h[a]
		IV	5 mg/kg q6–8h[a]

[a]Adjustments in dose or frequency of administration may be required in patients with renal impairment.
[b]Centers for Disease Control and Prevention recommendations for the treatment of gonococcal urethritis/cervicitis include concomitant therapy with azithromycin or doxycycline.
[c]After a single dose of 1 g ceftriaxone IM/IV.
[d]First-generation cephalosporin.
[e]Third-generation cephalosporin.
[f]Second-generation cephalosporin.

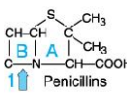


TABLE 231-2
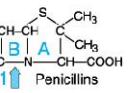
Adverse Events

Antibiotic Class	Pregnancy Category	Common Adverse Effects	Uncommon Adverse Effects
Penicillins	B	Hypersensitivity reactions: Exanthem, urticaria Diarrhea	Hypersensitivity reactions: Exfoliative dermatitis, SJS, vasculitis, AGEP Angioedema, anaphylaxis, serum sickness Anaphylactoid reaction Hepatitis, interstitial nephritis Neurotoxicity (high dosage) Pulmonary infiltrate with eosinophilia Immune-mediated hematologic reactions Pseudomembranous colitis
Cephalosporins	B	Hypersensitivity reactions as above Diarrhea	Hypersensitivity reactions as above Renal tubular necrosis Disulfiram-like reaction (specific) Thrombophlebitis (intravenous site) Serum sickness–like reaction (cefaclor, cefprozil) Pseudocholelithiasis (ceftriaxone)
Tetracyclines	D	Skin and nail hyperpigmentation (minocycline) Dental hyperpigmentation (infants, children) Gastrointestinal irritation	Photosensitivity (doxycycline) Photo-onycholysis Fixed drug eruption Pseudotumor cerebri Esophageal erosion/stricture Skeletal hypoplasia Serum sickness Renal toxicity Vestibular toxicity (minocycline) Fanconi syndrome (outdated tetracycline) Thyroid discoloration SJS, TEN Pancreatitis Blood dyscrasias (long-term use) Hypersensitivity reactions (various) Pseudomembranous colitis
Fluoroquinolones	C	Nausea, vomiting Cephalgia, dizziness	Exanthem, photosensitivity Delirium, seizure Tendon rupture, arthropathy (in the immature) QT prolongation Hepatitis (trovafloxacin—withdrawn from U.S. market)
Trimethoprim-sulfamethoxazole	C	Exanthem, photosensitivity Nausea, vomiting, anorexia Glossitis, stomatitis (Rare/severe reactions are more common in HIV/AIDS patients)	SJS, TEN, vasculitis, urticaria Pustular eruption, Sweet syndrome Cholestatic hepatitis, hepatic necrosis Blood dyscrasias Severe hypersensitivity reaction Cephalgia, hallucination, tremor Nephrolithiasis, interstitial nephritis
Lincosamides (clindamycin)	B	Diarrhea Exanthem, urticaria	Pseudomembranous colitis Erythema multiforme, SJS, TEN Elevated hepatic transaminase levels (reversible) Blood dyscrasias Neuromuscular blockade
Macrolides	B/C	Nausea, diarrhea, abdominal pain Dysgeusia (clarithromycin)	Cholestatic hepatitis Pseudomembranous colitis Prolonged QT interval, torsade de points Anaphylaxis SJS

AGEP = acute generalized exanthematous pustulosis; HIV/AIDS = human immunodeficiency virus/acquired immunodeficiency syndrome; SJS = Stevens-Johnson syndrome; TEN = toxic epidermal necrolysis.



involving inflamed skin, sites associated with a higher rate of bacteremia (such as mucosa, genitalia, and ear), and prolonged procedures, such as Mohs micrographic surgery, are less clear. In these situations, prophylaxis for patients with high- and moderate-risk conditions varies by institution and practitioner. If procedures must be performed on infected tissue antibiotic prophylaxis is probably warranted in the high- and moderate-risk groups due to higher rates of bacteremia.

Data concerning the risk of infection after dermatologic procedures in patients who have undergone total joint arthroplasty are sparse. Most infections involving joint replacements occur in the immediately postoperative period. Prophylaxis for patients at low risk whose joint replacement was performed more than 2 years earlier is not recommended. Procedures in patients at high risk, patients with joint prostheses less than 2 years old, and patients with vascular grafts or neurologic shunts are situations for which no current guidelines exist.

Although wound classification correlates well with infection rate, the wounds associated with most routine dermatologic procedures are difficult to categorize and are probably best classified between clean (class I) and clean-contaminated (class II) wounds. These wounds are at low risk of infection, and prophylactic antibiotic therapy to prevent surgical site infection is not warranted. This generally includes most Mohs micrographic surgical procedures, which have reported infection rates of 2 percent to 3 percent. However, the risk of infection increases when Mohs procedures involve mucosal sites or the ear, or closure is delayed. In these cases, use of prophylactic antibiotics may be warranted, although dedicated studies to address this question are lacking. There is much debate regarding the use of antibiotic prophylaxis after medium to deep facial laser resurfacing or chemical peels. Reported infection rates of these clean-contaminated wounds are less than 10 percent. Furthermore, some studies have demonstrated selection of pathogenic organisms and higher infection rates after prophylaxis in this setting. For this reason, antibiotic prophylaxis for these procedures is probably not warranted. Table 231-3 shows recommended first-line and alternative therapies for various bacterial infections.

PENICILLINS

Mechanism of Action

One of the oldest and largest groups of antibiotics, penicillins are members of the β-lactam family.[6] All penicillins have a nucleus composed of a thiazolidine ring and β-lactam ring, which is required for antibiotic activity. Different side chains alter activity and resistance to degradation, but all β-lactams share a similar bacteriocidal mechanism of action. They bind to specific penicillin-

[a]Rifampin is not recommended as monotherapy due to significant development of resistance.

binding proteins, inhibit cell wall peptidoglycan synthesis, and inactivate an inhibitor of autolytic enzymes present on bacterial cell walls.

There are several groups of penicillins, largely differentiated by their chemical structure and resistance to bacterial degradation. The natural penicillins exhibit the narrowest spectrum of activity and are susceptible to enzymatic degradation by β-lactamases. Penicillin G is the most useful drug in this group. Administered parenterally, it is active against *Streptococcus*, *Neisseria meningitidis*, *Clostridium* sp., spirochetes, *Pasteurella multocida*, *Eikenella corrodens*, *Erysipelothrix rhusiopathiae*, and non–β-lactamase-producing staphylococci. Penicillin G is the treatment of choice for *Treponema pallidum* infection in all forms. Penicillin V is the oral form of the drug and is generally less potent than penicillin G because of lower blood levels are achievable.

Aminopenicillins (ampicillin, amoxicillin), carboxypenicillins (carbenicillin, ticarcillin), and ureidopenicillins (piperacillin) provide a broader spectrum of activity. The ureidopenicillins have a profile of Gram-positive activity similar to that of the carboxypenicillins. Derived from ampicillin, they have greater activity against Gram-negative bacteria than do the carboxypenicillins. Amoxicillin, ticarcillin, and piperacillin are often coupled with β-lactamase inhibitors to enhance activity against *S. aureus*. The β-lactamase inhibitors include tazobactam, clavulanic acid, and sulbactam, and work best against β-lactamases encoded on plasmids.

The final group of penicillins (oxacillin, dicloxacillin, and nafcillin) is inherently β-lactamase resistant and exhibits excellent activity against *S. aureus*. Penicillins in this group have no activity against enterococci or enteric Gram-negative organisms. The β-lactamase–resistant penicillins remain an excellent choice for empiric treatment of uncomplicated SSTIs such as folliculitis, impetigo, furunculosis, and cellulitis in which community-acquired MRSA is not a suspected cause.

Pharmacokinetics

Absorption of oral penicillins is variable and depends on each compound's acid stability and the amount bound to food. Most oral penicillins should be taken at least 1 hour before or 1 hour after meals. Penicillins are excreted in breast milk in low quantities and are considered safe to use during breast-feeding.

Box 231-1

Indications for Penicillin Therapy

- Syphilis and non-venereal treponematoses
- Skin and soft-tissue infections caused by [illegible] sp. (erysipelas, scarlet fever, impetigo, etc.)
- Erysipeloid
- Anthrax (if sensitive)
- Lyme disease (when use of tetracyclines is contraindicated)
- Actinomycosis
- Listeriosis
- Leptospirosis
- Infected human and animal bites

Indications (Box 231-1)

Dosing Regimens

Dosing regimens for penicillins appear in Table 231-1. Dosing adjustment is necessary for patients with renal insufficiency.

Risks and Precautions

- Should be avoided in cases of known hypersensitivity to penicillin
- Levels are increased with concurrent use of probenecid and disulfiram
- Cause enhanced effect of methotrexate and warfarin

Complications

Hypersensitivity reactions are the most common adverse events reported with penicillins[7] (see Table 231-2). Reported incidence varies from 0.7 percent to 10.0 percent, and manifestations range from mild to severe (see Table 231-2). Penicillin hypersensitivity is probably overreported by patients, but 2 percent to 4 percent of true allergic reactions are life threatening. For patients with true penicillin allergy, use of another class of antibiotic is warranted. If penicillin allergy is uncertain and if penicillin treatment is required, skin prick testing may be performed to detect type I hypersensitivity, followed by intradermal testing if results are negative. Negative test results may be followed by a challenge dose of oral penicillin under observation. Approximately 10 percent to 20 percent of patients with a history of "penicillin allergy" have a positive skin test result, and approximately 3 percent of those with a negative skin test result and a history of allergy have an allergic response after a challenge dose of penicillin. These reactions tend to be mild. Patients with positive skin test results can undergo desensitization therapy when a β-lactam must be given.

CEPHALOSPORINS

Mechanism of Action

Cephalosporins are β-lactams with the same mechanism of action as penicillins; that is, they inhibit bacterial cell wall synthesis by blocking peptidoglycan incorporation.[8] Cephalosporins differ structurally from penicillins in that they have a dihydrothiazine ring instead of the thiazolidine ring of penicillins. Most cephalosporins have some activity against both Gram-positive organisms (excluding enterococci) and Gram-negative organisms, although the spectrum of activity varies widely within the group.

Pharmacokinetics

Cephalosporins are a chemically diverse class of antibiotics with unique pharmacokinetic and pharmacodynamic properties. Most orally administered cephalosporins can be taken without food. The esterified cephalosporins (cefuroxime and cefpodoxime) should be taken with food to prolong mucosal contact time, because they require enzymatic cleavage in the intestinal tract. Agents that lower the gastric pH may also reduce absorption of these two drugs. Cefaclor is an extended-release formulation and should also be given with food. Most cephalosporins are renally excreted. First-, second-, and third-generation cephalosporins are compatible with breast-feeding, and excretion in breast milk occurs in varying degrees.

Indications (Box 231-2)

Box 231-2

Indications for Cephalosporin Therapy

- Uncomplicated skin and soft-tissue infections due to [illegible] and [illegible] (first- and second-generation agents, plus cefdinir and cefditoren)
- Gonorrhea
- Lyme disease (ceftriaxone: Meningitis and late disease; cefuroxime: Early disease)
- Bacterial meningitis (ceftriaxone, cefotaxime)

Dosing Regimens (See Table 231-1)

Risks and Precautions

- Should be avoided in cases of known hypersensitivity to cephalosporins or penicillin (see Complications)
- Reduced absorption of cefdinir with concurrent use of antacids and iron salts
- Increased cyclosporin levels with concurrent use of ceftriaxone and ceftazidime
- Altered effect of warfarin with cefotetan, cefamandole, cefoperazone, cefixime, and cefaclor
- Impaired renal excretion of most cephalosporins with probenecid

Complications

Up to 20 percent of patients who are allergic to penicillin have a cross-reaction to cephalosporins, with most reactions in penicillin-allergic patients occurring to first- or second-generation cephalosporins.[9] The common β-lactam ring is responsible for the shared mechanism of action and some antigenic cross-reactivity, and the respective side chains for hypersensitivity reactions. Cephalosporins and penicillins with similar side chains are more likely to produce a cross-reactive hypersensitivity reaction in penicillin-allergic patients. Cefoxitin, cefamandole, cefaloram, cephalothin, and cephaloridine have side chains structurally similar to those of penicillin, whereas cefaclor, cephalexin, cefprozil, cephradine, and cefadroxil have side chains similar to those of amoxicillin or ampicillin. Patients reporting a penicillin allergy who have a negative result on a penicillin allergy skin test have no greater risk of an allergic reaction to β-lactams than does the general population. Cephalosporins, because they have a greater variety of metabolite structures than other β-lactams, are able to elicit cephalosporin-specific allergic responses (see Table 231-2).

TETRACYCLINES

Mechanism of Action

Tetracyclines inhibit bacterial protein synthesis by binding to the 30S ribosomal subunit and blocking transfer RNA binding to the messenger RNA–ribosome complex.[10] Doxycycline and minocycline are semi-synthetic second-generation tetracyclines and are the most commonly used in dermatology. More lipophilic than tetracycline, they generally exhibit greater activity, especially against *S. aureus* and community-acquired strains of MRSA.[11] As a class, tetracyclines have a broad spectrum of activity, including activity against many Gram-positive and Gram-negative bacteria, spirochetes, *Mycoplasma*, *Rickettsia*, *Chlamydia*, and some protozoa. Doxycycline is preferred therapy for the treatment of infections due to *Borrelia* sp., *Brucella* sp., *Chlamydia* sp., *Ehrlichia* sp. (monocytic and granulocytic ehrlichiosis), *Klebsiella granulomatis* (granuloma inguinale), *Coxiella burnetii* (Q fever), *Leptospira* sp., *Mycoplasma* sp., *Rickettsia* sp., and *Francisella tularensis*. It is also treatment for infections caused by *Actinomyces* sp., *Bacillus anthracis*, *Mycobacterium marinum*, and *Vibrio vulnificus*. In patients allergic to penicillins, doxycycline is commonly used to treat animal bites and syphilis. Tetracyclines can be helpful for the treatment of acne, rosacea, perioral dermatitis, autoimmune blistering disease (bullous pemphigoid, linear immunoglobulin A bullous dermatosis, and dermatitis herpetiformis), and confluent and reticulated papillomatosis (Gougerot-Carteaud syndrome), probably because of their anti-inflammatory properties.

Box 231-3

Indications for Tetracycline Therapy

- Actinomycosis
- Animal bites (*Eikenella corrodens*, *Pasteurella multocida*)
- Anthrax (*Bacillus anthracis*)
- *Bartonella* sp. infections
- Bacillary angiomatosis
- *Brucella* sp. infections
- Ehrlichiosis
- Granuloma inguinale
- Lyme disease
- Methicillin-resistant *Staphylococcus aureus* infections
- *Mycoplasma pneumoniae* infections
- *Nocardia* sp. infections
- Rickettsial diseases
- Rhinoscleroma
- Syphilis (penicillin-allergic patients)
- Tularemia
- *Vibrio vulnificus* infections
- *Yersinia pestis* infections

Pharmacokinetics

Tetracycline is incompletely absorbed, primarily in the stomach and small intestine, so it must be taken on an empty stomach. Doxycycline and minocycline are unaffected by the presence or absence of food and have longer half-lives than tetracycline, requiring less frequent dosing. They also have much greater lipid solubility than tetracycline, which allows excellent tissue penetration, with rapid availability in secretions of the prostate, respiratory tract, female reproductive tract, and bile. Nonetheless, patients should avoid concurrent ingestion of iron preparations, aluminum hydroxide gels, calcium and magnesium salts, or milk products, because these significantly lower absorption of the entire class. Tetracycline is excreted primarily by the kidneys, and patients with renal failure require dosing adjustment. Doxycycline is excreted in the feces, and no adjustments for renal or hepatic failure are necessary. Minocycline is largely metabolized before excretion but does not accumulate in patients with hepatic failure. Tetracyclines cross the placenta and appear in high concentrations in breast milk. Because of their ability to accumulate in developing bone and teeth, their use during pregnancy and lactation, and throughout childhood should be avoided.

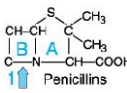
Indications (Box 231-3)

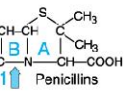
Dosing Regimens (See Table 231-1)

Risks and Precautions

- Require dosing adjustments in patients with renal failure (impaired excretion and anti-anabolic properties)
- May cause photosensitivity (doxycycline)
- Should be avoided in nursing or pregnant women and in children younger than 9 years of age
- Absorption impaired by calcium, magnesium, aluminum (other cations), iron, sodium bicarbonate, and cimetidine
- Increased metabolism of doxycycline with concurrent use of phenytoin, carbamazepine, barbiturates, and alcohol
- Lead to reduced insulin requirements in diabetic patients
- Lead to increased serum levels of digoxin, lithium, and warfarin
- Should not be used with methoxyflurane anesthesia (renal failure)

Complications (See Table 231-2)





CLINDAMYCIN

Mechanism of Action

Clindamycin is a lincosamide antibiotic derived through chemical modification of lincomycin.[12] Its absorption and spectrum of activity are better than those of its predecessor, which is now obsolete. Clindamycin binds to the bacterial 50S ribosomal subunit and inhibits protein synthesis through blockade of peptide chain initiation. The binding site overlaps the sites used by other antibiotics that bind the 50S subunit such as macrolides (erythromycin), which accounts for the antagonism noted between these drugs. Clindamycin facilitates opsonization and phagocytosis and decreases bacterial adhesion (to host cells) and production of staphylococcal exotoxin. Persistent binding at the 50S subunit leads to prolonged antibiotic effect against some organisms. Drug resistance occurs by mutation at the 50S binding site.

Pharmacokinetics

Clindamycin is not inhibited by food intake and reaches therapeutic levels in most tissues except cerebrospinal fluid. The drug preferentially accumulates in polymorphonuclear leukocytes, which may explain its benefit as treatment for abscesses. Clindamycin is primarily metabolized by the liver and excreted in the bile, although 10 percent is excreted in the urine. Dosing adjustments are necessary for patients with hepatic failure or combined hepatic and renal failure. The drug is not removed by dialysis.

Indications (Box 231-4)

Box 231-4

Indications for Clindamycin Therapy

- Uncomplicated skin and soft-tissue infections due to susceptible bacteria and protozoa
- Deep tissue infections: Streptococcal myositis, necrotizing fasciitis, or infections with ' PSXWMQ TI VWPKI RW conjunction with surgical débridement
- Surgical prophylaxis in penicillin-allergic patients
- Prophylaxis for recurrent staphylococcal infection
- Diabetic foot ulcers (in combination with agents for treatment of Gram-negative infection)
- Hidradenitis suppurativa
- Bacterial vaginosis

Dosing Regimens (See Table 231-1)

Risks and Precautions

- Require dosing adjustments in patients with hepatic failure
- Enhance neuromuscular blockade with tubocurare and pancuronium
- Possibly antagonistic with erythromycin

Complications

Clindamycin frequently causes gastrointestinal upset and diarrhea (2 percent to 20 percent of patients) and may occasionally cause pseudomembranous colitis attributed to *C. difficile*, a life-threatening complication reported in 0.1 percent to 10.0 percent of patients (see Table 231-2). Despite its classic association with clindamycin, pseudomembranous colitis may occur after administration of virtually any antibiotic. Treatment includes discontinuation of the drug and administration of metronidazole.

MACROLIDES

Mechanism of Action

Erythromycin is the prototypical macrolide antibiotic; derivatives include dirithromycin, clarithromycin, and azithromycin. All are bacteriostatic and inhibit bacterial protein synthesis by reversibly binding the 50S ribosomal subunit. Structural modifications of clarithromycin and azithromycin confer increased acid stability, tissue penetration, and spectrum of activity.[13] The macrolides have good but varied activity against Gram-positive pathogens, with clarithromycin more effective than erythromycin, which in turn shows more activity than azithromycin. Streptococcal resistance to macrolides is fairly common (up to 40 percent of group A isolates), and *S. aureus* may be variably susceptible to erythromycin. Streptococcal resistance to macrolides is class-wide rather than drug-specific.

Pharmacokinetics

Macrolides accumulate intracellularly in polymorphonuclear nuclear leukocytes and macrophages, which in part accounts for their activity against intracellular pathogens. Erythromycin base is absorbed in the small intestine and inactivated by gastric acidity; hence, it is available as enteric-coated tablets or capsules. (Food consumption lowers gastric pH, and taking the drug with food may delay absorption.) Erythromycin esters (erythromycin estolate, stearate, and ethylsuccinate) are less acid labile than the base form. Except in its extended-release formulation, which should be given with food, clarithromycin may be taken with or without food. Tissue concentrations of macrolides typically exceed plasma levels. Concentrations of erythromycin in breast milk are approximately 50 percent of maternal serum levels. Erythromycin can cross the placenta, but except for clarithromycin (which is pregnancy category C), the macrolides are category B drugs. Clarithromycin and azithromycin have longer half-lives, which allows less frequent dosing (see Table 231-1). Azithromycin remains in tissue longer and accumulates at high levels intracellularly (in tissue fibroblasts), which permits daily short-term dosing after a loading dose. Clarithromycin is metabolized by the liver and excreted by the kidneys. Patients with renal failure require dosing adjustments. Adjustments are not necessary for erythromycin, azithromycin, or dirithromycin, which primarily undergo hepatic metabolism. Erythromycin and clarithromycin interact with the cytochrome P_{450} (CYP) system, which can prompt numerous potential drug interactions (see Risks and Precautions). Erythromycin and clarithromycin inhibit CYP 3A4, and erythromycin also inhibits CYP 1A2.

Indications (Box 231-5)

Dosing Regimens (See Table 231-1)

Risks and Precautions

- May inhibit CYP 3A4, which leads to increased drug toxicity (increased serum levels) of warfarin, carbamazepine, buspirone, benzodiazepines, corticosteroids (methylprednisolone), β-hydroxy-β-methylglutaryl–coenzyme A reductase inhibitors, oral contracep-

Box 231-5

Indications for Macrolide Therapy

- Uncomplicated skin and soft-tissue infections (folliculitis, erysipelas, cellulitis, etc.)
- &EXSR IPEinfections (except Oroya fever, due to & FEGRBVQW
- Animal and human bites (4EVXYWPEQYX GVE) MORIPEGSXSHRW-azithromycin)
- Lyme disease
- Chlamydiosis
- Nontuberculous mycobacterial skin disease (clarithromycin)

tives, cyclosporine, tacrolimus, disopyramide, felodipine, ergot alkaloids
- May inhibit CYP 1A2, which leads to increased drug toxicity (increased serum levels) of theophylline, omeprazole
- Cause elevation of digoxin levels (due to change in drug metabolism by gut flora)
- Clarithromycin levels increased when given concurrently with fluconazole

Complications (See Table 231-2)

FLUOROQUINOLONES

Mechanism of Action

Fluoroquinolones are fluorinated derivatives of the first quinolone, nalidixic acid.[14] They work by inhibiting the action of bacterial topoisomerases II (DNA gyrase) and IV, which leads to impaired DNA replication, transcription, and repair. In Gram-positive organisms, the primary target is topoisomerase IV; in Gram-negative bacteria the target is topoisomerase II. Moxifloxacin, in particular, has been approved for the treatment of uncomplicated SSTIs. Some of the newer fluoroquinolones (levofloxacin, moxifloxacin) exhibit good activity against *Streptococcus*, but *S. aureus* organisms often develop resistance rapidly. These agents therefore should not be first-line therapy for uncomplicated SSTIs, but they may be useful in the treatment of complicated, polymicrobial, and/or Gram-negative infections such as diabetic ulcers or deep tissue infections. Ciprofloxacin and levofloxacin are effective agents for the treatment of gonorrhea, chlamydia, erysipeloid, granuloma inguinale, and chancroid (see the section on Indications). Ciprofloxacin, ofloxacin, levofloxacin, moxifloxacin, and gatifloxacin are effective against some *Mycobacterium* sp., including *M. tuberculosis*, *M. chelonae*, *M. fortuitum*, and *M. kansasii*, although available data are limited.

Pharmacokinetics

Fluoroquinolones are rapidly absorbed after oral ingestion, with a large volume of distribution. Food does not inhibit absorption. Unlike β-lactams, fluoroquinolones act in a concentration-dependent manner and can be administered twice daily. Most are excreted by the kidneys, and dosing adjustments for renal failure are usually necessary. Moxifloxacin is eliminated in the liver by conjugation with glucuronide and sulfate. None of the fluoroquinolones is removed by dialysis. Most are excreted in breast milk in small or almost negligible quantities, but rare side effects have occurred in breast-feeding infants. For example, ciprofloxacin has been associated with phototoxicity, pseudomembranous colitis, and green teeth on eruption. Norfloxacin is not found in the breast milk of mothers taking the drug, whereas ofloxacin and levofloxacin are excreted in smaller quantities than ciprofloxacin. Ciprofloxacin and ofloxacin are compatible with breast-feeding according to the American Academy of Pediatrics guidelines.

Box 231-6

Indications for Fluoroquinolone Therapy

AS FIRST-LINE THERAPY
- Anthrax
- Skin and soft-tissue infections (SSTIs) due to Gram-negative pathogens
- [illegible] infections (otitis externa, ecthyma gangrenosum, SSTIs) (ciprofloxacin)
- Rhinoscleroma

AS SECOND-LINE THERAPY
- [illegible] infections
- Chancroid
- Chlamydiosis
- Ehrlichiosis
- Erysipeloid
- Gonorrhea
- Granuloma inguinale
- [illegible] infections
- [illegible] infections

Indications (Box 231-6)

Dosing Regimens (See Table 231-1)

Risks and Precautions

- Show decreased bioavailability when taken with antacids (aluminum, magnesium, alum), iron, zinc, and sucralfate
- Inhibit the metabolism of theophylline and aminophylline (ciprofloxacin)
- Associated with arthropathy in studies of immature animals
- Can lead to tendon rupture (in patients with renal disease, patients undergoing hemodialysis, or patients taking steroids)
- Decrease the seizure threshold
- Decrease the metabolism of warfarin and cyclosporin

Complications (See Table 231-2)

TRIMETHOPRIM-SULFAMETHOXAZOLE

Mechanism of Action

Trimethoprim-sulfamethoxazole (co-trimoxazole) is a combination of trimethoprim (TMP) and sulfamethoxazole (SMX) in a 1:5 ratio. Both compounds reduce nucleic acid synthesis by inhibiting two enzymes in the bacterial tetrahydrofolic acid synthesis pathway. Together, these compounds exhibit synergistic action that is relatively specific to bacterial cells.

TMP-SMX is a broad-spectrum antibiotic with good activity against many aerobic Gram-positive cocci, including *S. aureus*, *S. pyogenes*, and *S. viridans*; it is often effective in the treatment of community-acquired MRSA infections.[11]

Pharmacokinetics

TMP and SMX are well absorbed but achieve different serum concentrations after administration of equal quantities of drug. A serum ratio of 1:20 (TMP/SMX) is necessary for optimal synergistic action against the largest variety of pathogens, which can be achieved by administering the drug in a fixed 1:5 ratio. Both compounds are rapidly distributed to tissues, including the cerebrospinal fluid and sputum. Excretion is via the kidneys.

Indications (Box 231-7)

Dosing Regimens (See Table 231-1)

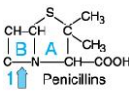
Risks and Precautions

- Causes more severe reactions in patients with human immunodeficiency virus infection/acquired immunodeficiency syndrome
- Prolongs prothrombin time in patients taking warfarin
- Contraindicated in patients taking methotrexate

Complications (See Table 231-2)

Box 231-7

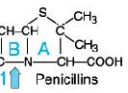
Indications for Trimethoprim-Sulfamethoxazole Therapy
- Community-acquired methicillin-resistant [illegible] infections
- [illegible] infections
- Uncomplicated skin and soft-tissue infections due to susceptible pathogens
- Granuloma inguinale
- Chancroid



NEWER OR LESS COMMONLY USED AGENTS

Although the aforementioned compounds comprise the vast majority of antibiotics used in dermatologic practice, several new or infrequently used medications bear mentioning for the treatment of complicated SSTIs or systemic infections caused by resistant pathogens.[17] In many hospitals, these drugs have restricted use, and their administration requires approval by an infectious disease specialist.

Vancomycin



Vancomycin is a glycopeptide antibiotic effective against Gram-positive bacteria only. It is used specifically to treat infections caused by Gram-positive organisms resistant to β-lactams or in cases in which their use is contraindicated.[18] In dermatology, vancomycin has been a first-line therapy for complicated and/or severe SSTIs caused by hospital-acquired MRSA. Vancomycin-resistant isolates of *S. aureus* and *Enterococcus faecium* have now been isolated. Vancomycin inhibits bacterial cell wall peptidoglycan synthesis. Dose is determined by the patient's weight (15 to 20 mg/kg) and frequency of administration by the patient's creatinine clearance. Because of this, renal function must be monitored during therapy. Potential adverse reactions include nephrotoxicity, ototoxicity, phlebitis at the injection site, hypersensitivity reactions, and leukopenia. "Red man syndrome," secondary to histamine release, is an uncommon reaction that can occur and is thought to be due to drug impurities. Use of more refined preparations and slower infusions minimize this reaction. Drug-induced linear immunoglobulin A disease is a rare cutaneous side effect. Two new glycopeptides, dalbavancin and oritavancin, are currently in clinical trials for the treatment of SSTIs.

Linezolid

Currently the only available oxazolidinone, linezolid has been approved by the U.S. Food and Drug Administration for the treatment of complicated SSTIs caused by MRSA as well as infections due to other drug-resistant Gram-positive organisms, including vancomycin-resistant *E. faecium* (VRE) and vancomycin-resistant *S. aureus*.[19] It is active against Gram-positive organisms (including anaerobes), as well as nontuberculous mycobacteria such as *M. chelonae* and *M. fortuitum*. Largely bacteriostatic, linezolid inhibits the initiation of protein translation by binding to the 23S portion of the 50S ribosomal subunit, a unique mechanism of action that minimizes cross-resistance to other antibiotics. Nonetheless, infections with linezolid-resistant enterococci have occurred. Although the drug is renally excreted, dosing adjustments for renal failure are not necessary. Linezolid is generally well tolerated, but reversible thrombocytopenia and leucopenia occur in approximately 2 percent of patients and seem to correlate with duration of therapy. This dictates monitoring of complete blood cell counts during therapy. Dosing for complicated infections is 600 mg twice daily, usually intravenously at first. The ability to convert to oral administration makes this drug an attractive option.

Quinupristin/Dalfopristin

Quinupristin/dalfopristin is a streptogramin antibiotic combination in a fixed 60:40 ratio.[17] Both quinupristin and dalfopristin irreversibly inhibit bacterial protein translation by binding to different sites on the 50S ribosomal subunit. They exhibit synergistic, largely bacteriocidal activity against a variety of multidrug-resistant Gram-positive organisms, including MRSA and VRE. Like linezolid, they have also been used in the treatment of vancomycin-resistant *S. aureus* infections. The recommended dosage is 7.5 mg/kg intravenously twice daily for at least 7 days, with lower dosages for patients with hepatic insufficiency. Patient tolerance of adverse effects, especially phlebitis (75 percent) if administered peripherally, arthralgia, and myalgia, can be a problem. Quinupristin/dalfopristin is metabolized by the liver and excreted in the bile. Elevation of hepatic transaminase and bilirubin levels has been reported, and concomitant administration with other drugs metabolized by the CYP 3A4 system is contraindicated. Quinupristin/dalfopristin should be used with caution in patients taking cyclosporine or agents that prolong the QT interval.

Daptomycin

Daptomycin is a cyclic lipopeptide, a new class of antibiotic derived from the fermentation of *Streptomyces roseosporus*.[20] Daptomycin has now been approved in the United States for the treatment of complicated SSTIs caused by *S. aureus* (including methicillin-resistant strains), *S. pyogenes*, *S. agalactiae*, *S. dysgalactiae* ssp. *equisimilis*, and *E. faecalis* (vancomycin-susceptible strains only). Its mechanism of action is unclear, but it acts rapidly and is bacteriocidal against Gram-positive bacteria. Dosing is 4 mg/kg intravenously every 24 hours for 7 to 14 days. Daptomycin is excreted primarily by the kidneys (78 percent), so that dosing adjustment is required for patients with renal impairment (creatinine clearance of less than 30 mL/min). The drug is generally well tolerated, with headache and constipation being the side effects reported most commonly (4 percent). The primary serious adverse effect is myopathy, which usually occurs at higher dosages.

Ertapenem

Ertapenem is a long-acting carbapenem with a broad spectrum of antimicrobial activity similar to that of the older carbapenems, imipenem-cilastin and meropenem.[17] Unlike imipenem, it has poor activity against *Pseudomonas* and enterococci. In clinical trials, it was comparable with piperacillin/tazobactam in the treatment of complicated SSTIs. It is active against both Gram-positive and Gram-negative aerobes and anaerobes, and should be reserved for the treatment of polymicrobial infections not sensitive to agents with more narrow spectra of activity. An extended half-life allows once-daily intravenous administration (1 g/day for 7 to 14 days), but the drug should be used cautiously in patients with renal impairment. Central nervous system effects and hypersensitivity reactions have been noted.

Tigecycline

Tigecycline is a glyclycycline antibiotic indicated for the treatment of complicated SSTIs due to susceptible organisms, which include MRSA and VRE.[21] A derivative of minocycline, tigecycline shares the same 30S ribosomal binding site and has a spectrum of activity similar to that of the classic tetracyclines. However, tigecycline demonstrates a greater volume of distribution, better activity against organisms with tetracycline resistance, and better activity against *Streptococcus* sp. Tigecycline dosing is 50 mg intravenously twice daily after a 100-mg loading dose. Dosing adjustments for renal impairment are not required, but lower dosing is necessary for patients with severe hepatic disease. The same precautions taken for the tetracycline class of antibiotics should be observed for tigecycline.

CHAPTER 232

Antiviral Drugs

Christine M. Hay
Richard C. Reichman

Antiviral drugs have been developed at an extraordinary pace during the past two decades. Progress has been accelerated by advances in knowledge of the molecular biology and pathogenesis of viruses, of which human immunodeficiency virus (HIV) has been the most notable. This chapter focuses on drugs to treat those viral infections that are most likely to be encountered by dermatologists, such as those caused by herpes simplex virus (HSV) and varicella-zoster virus (VZV). Antiviral drugs used to treat cytomegalovirus (CMV) infections, hepatitis, and influenza, and antiretroviral drugs to combat HIV infection are discussed in less depth, and the reader is referred to reviews of these subjects for more information.

DRUGS FOR THE TREATMENT OF HERPESVIRUS INFECTIONS (See Chaps. 193 and 194)

Acyclovir

MECHANISM OF ACTION Acyclovir, 9-[(2-hydroxyethoxy)methyl] guanine, is an antiviral drug widely used for the treatment of HSV and VZV infections.[1] The active antiviral moiety of acyclovir is acyclovir triphosphate, which is a potent inhibitor of certain herpesvirus-induced DNA polymerases but has relatively little effect on host cell DNA polymerase. Acyclovir triphosphate also acts as a terminator of the nascent viral DNA chain because it lacks the 3′ hydroxyl group. The initial phosphorylation of acyclovir to acyclovir monophosphate is efficiently carried out by HSV- and VZV-induced thymidine kinases but not by cellular kinases. Thus, acyclovir monophosphate is concentrated in virus-infected cells, which contributes to its highly selective mechanism of action.[2]

PHARMACOKINETICS Acyclovir is available in oral, intravenous, and topical formulations. The oral bioavailability of acyclovir is low (15 percent to 30 percent). Acyclovir is almost entirely eliminated by the renal route, largely unmetabolized (85 percent). Therefore, dosage reductions are required for patients with creatinine clearances of less than 50 mL/min.[3] Acyclovir is widely distributed in body fluids, including cerebrospinal fluid, vesicle fluids, and vaginal secretions. Acyclovir is available as a 5 percent ointment in a polyethylene glycol base in the United States, and topical administration results in detectable drug concentrations in lesions but little, if any, systemic absorption.

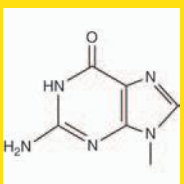
INDICATIONS

- Treatment of symptomatic primary or recurrent mucocutaneous HSV-1 or HSV-2 infection
- Suppression of recurrent HSV-1 and HSV-2 infections
- Treatment of mucocutaneous HSV infections in immunocompromised patients
- Prevention of perinatal HSV-1 and HSV-2 infection and treatment of neonatal HSV infection
- Treatment of primary VZV infection in adults and immunocompromised children
- Treatment of VZV infection to reduce the risk of postherpetic neuralgia
- Treatment of HSV-1 encephalitis
- Post-exposure prophylaxis and treatment for herpes simiae after monkey bite

DOSING REGIMENS (Table 232-1)

INITIATION OF THERAPY In general, therapy for mucocutaneous HSV disease should begin as soon after lesions are seen as possible. Treatment for episodic recurrent disease should begin during the prodromal period.[5,6] Treatment for varicella should begin within 24 hours of the onset of the rash. Treatment for herpes zoster in the immunocompetent host is of benefit only if started within 3 days of the onset of the rash.

ANTIVIRAL DRUGS AT A GLANCE



- Antivirals are now approved for treatment of a variety of viral infections.
- Antiviral resistance is a growing concern, especially in the treatment of human immunodeficiency virus infection.
- Antivirals work in a number of different ways, and their spectra of activity can be very specific (amantadine) or quite broad (ribavirin).
- The use of prodrugs of acyclovir and ganciclovir has greatly increased the oral bioavailability of these agents, which allows outpatient treatment of many herpesvirus infections.

MONITORING OF THERAPY Because acyclovir is renally excreted, dosages must be adjusted for patients with a creatinine clearance level of less than 50 mL/min. Assays for drug level are not clinically available.

RISKS AND PRECAUTIONS

- Renal (5 percent)[7]
  - Crystallization in renal tubules leading to obstructive nephropathy
  - Interstitial nephritis

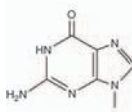


TABLE 232-1
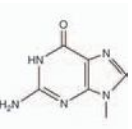
Dosing Regimens for Acyclovir

CONDITION	DOSAGE	ROUTE	DURATION
Primary HSV infection, immunocompetent host	400 mg tid	Oral	7–10 days
Recurrent genital HSV infection, immunocompetent host	400 mg tid SV 800 mg tid	Oral Oral	5 days 2 days[4]
Recurrent oral labial HSV infection, immunocompetent host	400 mg 5×/day SV 5% cream 6×/day	Oral Topical	5 days 7 days
Oral labial HSV infection, immunocompromised host	5 mg/kg q8h SV 400 mg 5×/day	IV Oral	7 days 14–21 days
Perinatal HSV infection	10–20 mg/kg q8h	IV	10–21 days
Chronic suppression of HSV infection	400 mg bid SV 800 mg qd	Oral	
HSV-1 Encephalitis	10 mg/kg q8h	IV	14–21 days
Varicella: adolescent/adult	800 mg 5×/day	Oral	5–7 days
Varicella: pneumonia or third trimester pregnancy	800 mg 5×/day SV 10 mg/kg q8h	Oral IV	5 days 5 days
Herpes zoster: normal host or not severe disease in immunocompromised host	800 mg 5×/day	Oral	7–10 days
Herpes zoster: severe disease or immunocompromised host	10–12 mg/kg q8h	IV	7–14 days

HSV = herpes simplex virus.



- Central nervous system (1 percent)[8]
  - Lethargy
  - Tremors
  - Confusion
  - Seizures
- Other (rare)
  - Phlebitis with intravenous administration
  - Rash
    - Recall dermatitis[9]
    - Contact dermatitis
    - Fixed drug eruptions
  - Elevated values on liver function tests
  - Neutropenia

COMPLICATIONS Acyclovir is generally well tolerated. The major toxicity associated with acyclovir is renal, as a result of crystallization of the drug in renal tubules, which has been reported with high dosage, dehydration, or rapid intravenous administration. Interstitial nephritis associated with acyclovir use has also been reported.[7] Central nervous system toxicity has been described, including lethargy, tremors, obtundation, and seizures.[8] These side effects have usually been associated with high plasma levels of acyclovir and with underlying diseases involving the central nervous system.

Valacyclovir

MECHANISM OF ACTION AND PHARMACOKINETICS Valacyclovir, 2-[2-amino-1,6-dihydro-6-oxo-9*H*-purin-9-yl-methoxy] ethyl-L-valinate hydrochloride, is the L-valine ester of acyclovir. It was developed to provide increased oral bioavailability of acyclovir.[10] Valacyclovir is rapidly absorbed from the gastrointestinal tract and is converted almost entirely to acyclovir through intestinal and hepatic esterases. Thus, the mechanism of action and spectrum of activity of valacyclovir are that of acyclovir. After a 1-g oral dose of valacyclovir, peak plasma concentrations of acyclovir of 5.7 μg/mL are achieved in 1.75 hours, with area-under-the-curve concentrations that are similar to those achieved with 5 mg/kg of acyclovir given intravenously.[11] The pharmacokinetics of valacyclovir are those of the parent compound, acyclovir.

INDICATIONS

- Treatment of initial and recurrent HSV genital infections[12]
- Suppression of frequently recurring genital HSV infections[13]
- Treatment of herpes zoster[14]

DOSING REGIMENS (Table 232-2)

INITIATION OF THERAPY As with its parent compound, acyclovir, valacyclovir therapy should be initiated as soon as possible after the appearance of an HSV or VZV rash.

RISKS AND PRECAUTIONS In addition to the effects noted with acyclovir,

- Thrombotic thrombocytopenic purpura/hemolytic uremic syndrome (TTP/HUS), seen in patients with advanced HIV disease and in transplant recipients receiving dosages of 8 g/day

COMPLICATIONS Adverse effects are those that would be expected with acyclovir. However, severe and even fatal cases of TTP/HUS have been reported in patients with acquired immunodeficiency syndrome (AIDS) and transplant recipients who were taking high dos-

TABLE 232-2

HSV = herpes simplex virus.

ages of valacyclovir.[15] The basis for and causal relationship to valacyclovir of these occurrences have not been established, and TTP/HUS has not been reported in patients taking conventional dosages (up to 3 g/day) of valacyclovir.

Famciclovir and Penciclovir

MECHANISM OF ACTION Famciclovir, [9-(4-hydroxy-3-hydroxy-methylbut-1-yl) guanine, is a prodrug of penciclovir, [9-(4-hydroxy-3-hydroxy-3-hydroxymethylbut-1-yl) guanine]. Penciclovir is phosphorylated to penciclovir triphosphate. The initial phosphorylation of penciclovir to penciclovir monophosphate is carried out by HSV- or VZV-induced thymidine kinases in a manner analogous to that of the initial phosphorylation of acyclovir. Phosphorylation to diphosphate and triphosphate forms of penciclovir is carried out by cellular kinases. Penciclovir triphosphate inhibits viral DNA polymerases and also inhibits extension of the nascent viral DNA chain.[16] Because of the presence of the hydroxyl group on the acyclic side chain of penciclovir, some DNA chain extension may occur.

PHARMACOKINETICS Famciclovir is available as an oral formulation, which is converted to penciclovir by deacetylation and oxidation in the liver and intestine. The bioavailability of famciclovir is 77 percent, and a peak penciclovir plasma concentration of 3.3 μg/mL is reached 1 hour after oral administration of 500 mg of famciclovir.[17,18] The plasma half-life of penciclovir is 2 hours, and 60 percent to 70 percent of the drug is excreted unchanged in the urine by both glomerular filtration and tubular secretion. The dosage of penciclovir should be reduced in cases of advanced renal dysfunction.[17] Compared with the intracellular half-life of acyclovir triphosphate, that of penciclovir triphosphate is markedly prolonged in HSV-infected cells (10 to 20 hours) and VZV-infected cells (9 hours).[19] This prolonged intracellular half-life is the rationale for the longer interval of administration of famciclovir (every 12 hours), compared to that recommended for acyclovir (every 4 hours). Penciclovir is also available as a 1 percent ointment for the treatment of recurrent oral HSV.[20]

INDICATIONS

- Treatment of initial and recurrent HSV genital infections[21]
- Suppression of frequently recurring genital HSV infections[22]
- Treatment of herpes zoster[23]

TABLE 232-3
Dosing Regimens for Famciclovir and Penciclovir

CONDITION	DOSAGE	ROUTE	DURATION
Primary HSV infection, immunocompetent host	250 mg tid	Oral	7–10 days
Recurrent genital HSV infection, immunocompetent host	125 mg bid or 1000 mg bid	Oral Oral	5 days 1 day
Recurrent oral labial HSV infection, immunocompetent host	500 mg bid SV 1% penciclovir cream q2h	Oral Topical	7 days 5 days or until lesions healed
Oral labial HSV infection, immunocompromised host	500 mg bid	Oral	7 days
Chronic suppression of HSV infection	250 mg bid	Oral	Up to 1 yr
Varicella: adolescent/adult	500 mg tid	Oral	5 days
Herpes zoster: normal host or not severe disease in immunocompromised host	500 mg tid	Oral	7 days

HSV = herpes simplex virus.

DOSING REGIMENS (Table 232-3)

RISKS AND PRECAUTIONS Famciclovir is generally very well tolerated. Dosage should be reduced if creatinine clearance is less than 60 mL/min. The drug may cause the following:

- Headache
- Nausea
- Diarrhea
- Dizziness

COMPLICATIONS Famciclovir is well tolerated, and serious clinical and laboratory toxicities are uncommon. Prolonged high-dose administration of famciclovir to rats was associated with an increased incidence of mammary adenocarcinomas in females, but the clinical significance of this observation is unknown.

Trifluridine

MECHANISM OF ACTION AND PHARMACOKINETICS Trifluridine, 5-trifluoromethyl-2′-deoxyuridine, is a pyrimidine nucleoside analog. Trifluridine monophosphate is an irreversible competitive inhibitor of thymidylate synthetase, and trifluridine triphosphate inhibits HSV DNA polymerase. Trifluridine triphosphate also inhibits cellular DNA polymerases, although to a lesser extent than viral DNA polymerases. Because of systemic toxicity, trifluridine is approved only for topical application in the form of a 1 percent ophthalmic aqueous solution. The elimination half-life for the ophthalmic solution is 12 to 18 minutes.

INDICATIONS

- Treatment of primary HSV conjunctivitis
- Treatment of recurrent HSV epithelial keratitis[24]
- Treatment of acyclovir-resistant mucocutaneous HSV infections in patients with AIDS[25]

DOSING REGIMENS (Table 232-4)

RISKS AND COMPLICATIONS

- Mild burning
- Palpebral edema
- Punctate keratopathy
- Stromal edema

DRUGS FOR THE TREATMENT OF CYTOMEGALOVIRUS INFECTIONS

Ganciclovir

Valganciclovir

MECHANISM OF ACTION AND PHARMACOKINETICS Valganciclovir, L-valine 2-[(2-amino-1,6-dehydro-6-oxo-9H-purin-9-yl) methoxy]-3-hydroxypropyl ester, is the L-valyl ester of ganciclovir. It acts as a prodrug for ganciclovir in a manner similar to the way in which valacyclovir serves as a prodrug for acyclovir and is the usual form of ganciclovir used in the outpatient setting. After oral administration, valganciclovir is rapidly converted to ganciclovir by intestinal and hepatic esterases. The oral availability of valganciclovir as ganciclovir is approximately 60

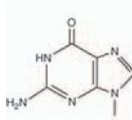

TABLE 232-4
Dosing Regimens for Trifluridine

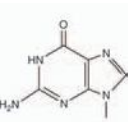
CONDITION	DOSAGE	ROUTE	DURATION
Primary HSV conjunctivitis	1 drop 1% solution q2h (maximum, 9 drops/24 h)	Topical	Maximum, 21 days
Recurrent HSV epithelial keratitis	1 drop 1% solution q2h (maximum, 9 drops/24 h)	Topical	Maximum, 21 days
Acyclovir-resistant HSV infection in AIDS	1% solution q8h	Topical	10–14 days or until lesions resolve

AIDS = acquired immunodeficiency syndrome; HSV = herpes simplex virus.

TABLE 232-5
Dosing Regimens for Valganciclovir

CONDITION	DOSAGE	ROUTE	DURATION
CMV retinitis	Induction: 900 mg bid	Oral	21 days
	Maintenance: 900 mg qd	Oral	Until CD4 count > 100 after 6 mo of HAART

CMV = cytomegalovirus; HAART = highly active antiretroviral therapy.



percent and is increased by administration with food. After a 900-mg dose of valganciclovir, the maximum plasma concentration of ganciclovir is 5.61 μg/mL, and the plasma concentration–time curve is similar to that achieved with ganciclovir given intravenously at a dose of 5 mg/kg.[40] The toxicities of valganciclovir are those of its active compound, ganciclovir.

INDICATIONS

- Treatment of CMV retinitis in patients with AIDS[41]
- Suppression and prevention of CMV disease in transplant recipients[42,43]

DOSING REGIMENS (Table 232-5)

RISKS AND COMPLICATIONS

Risks and complications are similar to those of its parent compound, ganciclovir.

Foscarnet

MECHANISM OF ACTION

Foscarnet, trisodium phosphonoformate, is a pyrophosphate-containing compound that noncompetitively inhibits viral DNA polymerases at the pyrophosphate binding site.[44] In contrast to the nucleoside analogues, foscarnet does not require phosphorylation for its antiviral activity and is therefore active against viruses that are resistant to acyclovir, famciclovir, or ganciclovir because of absent or altered kinase activities.

PHARMACOKINETICS

Foscarnet is currently available only as an intravenous preparation that has poor solubility and must be administered by an infusion pump in a dilute solution over 1 to 2 hours. The plasma half-life of the drug consists of an initial phase of 4 to 8 hours and a terminal component of 88 hours or longer, which reflects a deposition in bone of up to 20 percent of the dose.[45] Eighty percent of the dose is excreted unmetabolized by the kidney, and the dosage should be reduced in patients with renal dysfunction.[46]

INDICATIONS

- Treatment of CMV retinitis in patients with AIDS[47]
- Treatment of CMV colitis[33]
- Treatment of CMV polyradiculopathy in combination with ganciclovir[48]
- Treatment of acyclovir-resistant HSV infections[25]
- Treatment of ganciclovir-resistant CMV infections[49]

DOSING REGIMENS (Table 232-6)

RISKS AND COMPLICATIONS

- Renal (30 percent)[50]
  - Increased creatinine levels
  - Proteinuria
  - Nephrogenic diabetes insipidus
  - Hypokalemia, hypocalcemia, hypomagnesemia
- Headache
- Fatigue
- Fever
- Seizures
- Low white blood cell count, anemia

MONITORING OF THERAPY

The major toxicity associated with foscarnet involves the kidney, and use of the drug requires close monitoring of renal function, particularly during the initial phases of therapy. Saline hydration before administration and slow infusion of the drug appear to reduce nephrotoxicity. Electrolyte abnormalities such as hypocalcemia and hypercalcemia, hypophosphatemia and hyperphosphatemia, hypomagnesemia, and hypokalemia have been described. The levels of these electrolytes should be checked frequently.[50]

Cidofovir

MECHANISM OF ACTION

Cidofovir, (S)-1-[3-hydroxy-2(phosphonylmethoxy)-propyl] cytosine, is a phosphonate nucleotide analog. Cidofovir does not require initial phosphorylation by virus-induced kinases but is converted by host cell enzymes to cidofovir diphosphate, which is a competitive inhibitor of viral DNA polymerases and, to a lesser extent, of host cell DNA polymerases.[51]

PHARMACOKINETICS

Cidofovir is approved for intravenous administration. A topical formulation is also available. An intravenous dose of 5 mg/kg results in a peak plasma concentration of 11.5 μg/mL. The plasma half-life of cidofovir is 2.6 hours, and the drug is excreted almost entirely by the kidney.[52] Cidofovir diphosphate has a markedly prolonged intracellular half-life (more than 48 hours), which is the basis for the recom-

TABLE 232-6
Dosing Regimens for Foscarnet

CONDITION	DOSAGE	ROUTE	DURATION
CMV retinitis	Induction: 90 mg/kg q12h	IV	14–21 days
	Maintenance: 90 mg/kg q24h	IV	Until CD4 count >100 on 6 mo of HAART
Acyclovir-resistant HSV infection	40 mg/kg q8h SV	IV	
	60 mg/kg q12h	IV	2–3 wk or until clinical resolution

CMV = cytomegalovirus; HAART = highly active antiretroviral therapy; HSV = herpes simplex virus.

mended dosing regimen of 5 mg/kg twice a week for the first 2 weeks, followed by one dose every 2 weeks.[52–54]

INDICATIONS Indications for treatment with cidofovir include the following:

- CMV retinitis in AIDS[55]
- Treatment of resistant HSV and CMV infections[56]

Cidofovir also has antiviral activity against poxviruses, including vaccinia and variola (smallpox),[57] monkeypox,[58] and molluscum contagiosum.[59] It has been used successfully in topical form[60] for the treatment of the lesions of human papillomavirus infection, Kaposi sarcoma, and HSV infection, although it is not approved for these uses.

DOSING REGIMENS (Table 232-7)

RISKS AND COMPLICATIONS

- Renal tubular damage[61]
  - Dose-dependent proximal tubular injury (Fanconi-like)
  - Proteinuria
  - Elevated serum creatinine levels
- Rash
- Nausea (48 percent)
- Alopecia (16 percent)
- Fever
- Myalgia

PRECAUTIONS Hydration, along with the administration of probenecid before and after infusion, appears to protect against nephrotoxicity. Properly timed intravenous prehydration with normal saline and oral administration of probenecid must be carried out with each cidofovir infusion. Renal function must be monitored before each dose.

Adefovir Dipivoxil

Entecavir

Ribavirin

Interferons

MECHANISM OF ACTION Interferons are cytokines that have broad antiviral, immunomodulating, and antiproliferative effects. The antiviral activities of interferons are multiple and complex and vary according to the cell type and virus. Interferons have been studied as treatment for a variety of viral infections as well as for a number of diseases of non-infectious etiology. For viral infections, interferon-α has been studied most extensively.

TABLE 232-7
Dosing Regimens for Cidofovir

CONDITION	DOSAGE	ROUTE	DURATION
CMV retinitis	Induction: 5 mg/kg every week	IV	2 wk
	Maintenance: 5 mg/kg every 2 wk	IV	Until CD4 count > 100 after 6 mo on HAART

CMV = cytomegalovirus; HAART = highly active antiretroviral therapy.
Note: Cidofovir IV administration must be accompanied by prehydration and probenecid.

PHARMACOKINETICS Interferon may be administered intravenously or, more commonly, subcutaneously or intramuscularly. The plasma half-life is 2 to 3 hours after intravenous administration of interferon-α and 4 to 6 hours after subcutaneous or intramuscular administration.[85] A markedly prolonged half-life is seen with the use of "pegylated" interferons.

INDICATIONS

- Condyloma acuminata (intralesional treatment)[86]
- Chronic hepatitis C infection in combination with ribavirin[87–90]
- Chronic hepatitis B infection[91,92]

DOSING REGIMENS (Table 232-8)

RISKS AND COMPLICATIONS[93]

- Flu-like syndrome
- Myalgia/arthralgia
- Gastrointestinal symptoms
- Granulocytopenia/thrombocytopenia
- Neurotoxicities
- Alopecia
- Hepatotoxicity
- Autoantibody formation

PRECAUTIONS Interferon-α can cause serious depression in up to one-third of users.[94,95] Interferon-α should not be used to treat hepatitis B–related cirrhosis or decompensated liver disease because hepatitis flares are common and may lead to further decompensation.

DRUGS FOR THE TREATMENT OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Drug treatment of HIV infection has become a complex undertaking requiring specialized training, experience, and ongoing involvement in patient care.[96,97] Studies have demonstrated that patients cared for by experienced HIV practitioners have better outcomes than patients treated by less experienced physicians.[98–100] Currently there are 22 approved antiretroviral drugs, and 6 fixed-dose combinations. Several additional drugs, including members of entirely new classes of compounds, are likely to become available in the very near future. Strategies for the use of antiretrovirals have emerged from the results of large-scale clinical trials as well as from advances in the understanding of the pathogenesis of HIV-1 infection. These studies have established three important principles on which recommendations for the use of antiretroviral drugs are based: (1) combination therapy with at least three drugs should be used to maximize clinical and antiviral effects and to minimize the emergence of resistant viruses; (2) viral load, as well as CD4 counts, should be monitored as important measures of the effectiveness of antiviral therapy; and (3) phenotypic and/or genotypic assays to detect potential resistance of HIV isolates to antiretroviral drugs should be performed before the initiation of therapy and subsequently should virologic failure occur after ther-

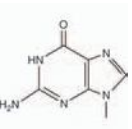
TABLE 232-8
Dosing Regimens for the Interferons

CONDITION	DOSAGE	ROUTE	DURATION
Condyloma acuminata	IFN-α2b 1 million units 3×/wk	Intralesional	3 wk
Chronic hepatitis C (with ribavirin)	PegIFN-α2a 180 μg once a week SV PegIFN-α2b 1.5 μg/kg once a week	Subcutaneous	Dependent on response and genotype
Chronic hepatitis B	PegIFN-α2a 180 μg once a week SV PegIFN-α2b 1.5 μg/kg once a week	Subcutaneous	At least 1 yr

IFN = interferon; PegIFN = peginterferon.

apy is begun. Results of these tests can be used to help design optimal drug regimens. These principles, along with examples of regimens to be used in specific clinical settings, are outlined in guidelines put forth by national and international expert panels.[101,102] Because of the complex nature of antiretroviral therapy and the rapid development of new agents, this section does not attempt to provide a thorough discussion of all drugs, but rather focuses on the most commonly used agents, including representative compounds from each major class.

Nucleoside and Nucleotide Reverse Transcriptase Inhibitors



Seven nucleoside and one nucleotide reverse transcriptase inhibitors (NRTIs) are licensed for use in the treatment of HIV infection in the United States. Zalcitabine is toxic, is rarely used, and is not discussed further.

MECHANISM OF ACTION AND RESISTANCE

After passive uptake by host cells, NRTIs are phosphorylated by cellular kinases to their active triphosphate forms, which compete with the naturally occurring deoxynucleoside substrates for binding to reverse transcriptase (RT). Subsequently, they are incorporated into the growing DNA chain, which results in chain termination. The compounds are active against HIV-1, HIV-2, and other retroviruses.[103,104]

Because of the high rate of HIV replication and the lack of a proofreading function in RT, a mutation may arise at each nucleotide position as often as 104 times per day in an untreated person.[105] Thus, mutations that confer resistance may be present before therapy is begun. After initiation of therapy, resistance may develop if such mutations are allowed to accumulate because of incomplete suppression of viral replication by the therapeutic regimen. Genotypic resistance has been observed against all antiretrovirals currently in use and was initially described for zidovudine, the first NRTI to be widely used clinically.[106] Resistance to zidovudine generally occurs with the cumulative development of characteristic mutations at codons 70, 215, 41, 67, 210, and 219.[107]

PHARMACOKINETICS Like other antiretroviral drugs, NRTIs are primarily given by the oral route. In general, these drugs are well absorbed from the gastrointestinal tract, although there is considerable variation among them. In addition, there are differences in bioavailability when they are administered with and without food and differences in both serum and intracellular half-lives. Distribution, metabolism, and excretion also vary considerably among different agents. Specific prescribing directions should be consulted before administration.

INDICATIONS

- Primary or initial treatment of HIV infection. Two drugs from this class plus a nonnucleoside RT inhibitor or a protease inhibitor are recommended for initial treatment of HIV infection.[101] Dual nucleoside combinations represent the most common backbone of antiretroviral regimens. Two nucleosides are generally combined with either a nonnucleoside RT inhibitor or a protease inhibitor for use in initial therapy. Recommended combinations include zidovudine + lamivudine, tenofovir + emtricitabine, and abacavir + lamivudine, all of which are available as fixed-dose combination products (under the trade names Combivir, Truvada, and Epzicom, respectively).
- Management of previously treated patients who have experienced treatment failure. The cause of treatment failure can often be determined by careful history taking. Important considerations include the patient's adherence to the treatment regimen, tolerability of medications, need for concomitant food or fasting for optimal drug absorption, and drug resistance. It is best to perform resistance testing while patients are taking the failing regimen or within 4 weeks of discontinuance of the regimen. It is generally recommended that at least two fully active drugs be used when a new therapeutic regimen is designed. Drugs from the NRTI class are frequently used in such regimens, although HIV resistance often compromises their effectiveness.
- Treatment of hepatitis B infection. Lamivudine, in a dosage of 100 mg daily, decreases levels of HBV DNA in plasma and produces beneficial histologic and chemical effects in many patients with chronic hepatitis B,[129] although monotherapy is often associated with development of viral resistance.[130]

DOSING REGIMENS

INITIATION OF THERAPY Most experts agree that antiretroviral therapy should be initiated in all patients with a history of an AIDS-defining illness and in patients with a CD4 count of less than 200 $CD4^+$ T cells/mm^3 even if asymptomatic.[101,102] In addition, therapy should be offered to those with CD4 counts between 201 and 350 $CD4^+$ T cells/mm^3. Some clinicians also consider therapy for patients with CD4 counts higher than 350 $CD4^+$ T cells/mm^3 and plasma HIV RNA levels higher than 100,000 copies/mL. The decision to initiate antiretroviral therapy in an asymptomatic patient must be made with care. Treatment of HIV infection is a lifelong proposition, and adherence to therapy is a critical component of treatment success. Thus, considerable attention must be paid to counseling and education of the patient.

MONITORING OF THERAPY The two surrogate markers used to monitor response to therapy are the $CD4^+$ T-cell count and the plasma HIV RNA level, or viral load. The CD4 count is the major laboratory indicator of immunocompetence in this patient population and can be expected to increase considerably in response to appropriate antiretroviral therapy. A significant change in CD4 count has been defined as either a 30 percent change in absolute count or a 3 percent change in CD4 percentage. In general, the CD4 count is measured every 3 to 6 months to assess the immunologic response to treatment. The viral load is a direct indicator of virus replication and is routinely used as a measure of antiviral drug effect. The minimal change in viral load that is considered to be significant is a threefold change or 0.5 $\log_{10}$ copies/mL. The goal of treatment is to take the viral load below the limits of detection of the test that is being used to measure HIV RNA. Viral load determinations are generally made at the same intervals as CD4 counts.

RISKS AND COMPLICATIONS Common side effects seen with zidovudine treatment include bone marrow suppression and gastrointestinal intolerance. Stavudine is generally well tolerated but is associated with lipoatrophy and lactic acidosis, whereas the primary toxicities of didanosine are pancreatitis and peripheral neuropathy. Abacavir is associated with an uncommon but potentially life-threatening hypersensitivity reaction. Tenofovir may produce headache and nausea; it elevates levels of didanosine and decreases levels of atazanavir. Lamivudine is among the best tolerated antiretroviral drugs but may produce neutropenia.

General toxicities associated with NRTIs, seen more commonly with some agents than with others, include the following:

- Lactic acidosis with hepatic steatosis
- Progressive ascending neuromuscular weakness syndrome
- Dyslipidemia
- Fat maldistribution and lipoatrophy

PRECAUTIONS Because of concerns regarding the development of resistance, NRTIs should never be administered as single or dual agents for the treatment of established HIV infection. In addition, certain combinations should be avoided, including the three-nucleoside regimen of abacavir + tenofovir + lamivudine (unacceptable virologic failure)[131]; the three-nucleoside regimen of didanosine + tenofovir + lamivudine (unacceptable virologic failure)[132]; didanosine + stavudine (increased toxicity)[133]; and stavudine + zidovudine (antagonistic).[134,135] All patients receiving NRTIs need to be monitored for lactic acidosis, hepatitis, bone marrow suppression, and development of neurologic side effects and pancreatitis.

Nonnucleoside Reverse Transcriptase Inhibitors

Three nonnucleoside reverse transcriptase inhibitors (NNRTIs) are licensed for use in the treatment of HIV infection in the United States: nevirapine, delavirdine, and efavirenz.

MECHANISM OF ACTION AND RESISTANCE NNRTIs are noncompetitive inhibitors of RT, bind at sites different from the nucleoside binding site, and are active against HIV-1 but not HIV-2.[136] Resistance to the nucleoside analogues does not impinge on the activity of NNRTIs. In fact, some mutations associated with resistance to nucleoside analogues may actually produce hypersusceptibility to NNRTIs.[137–139] However, mutations that confer resistance to one NNRTI often produce cross-resistance to other members of this class. Thus, virologic failure after treatment with one of these drugs often predicts failure with the other NNRTIs as well.[140] Mutations at positions 103 and 181 often confer resistance to all three of the currently available NNRTIs. Other mutations at positions 101, 106, 188, 190, and 236 may also contribute.[141]

PHARMACOKINETICS Nevirapine has a bioavailability of more than 90 percent and a plasma half-life of 24 hours. It is metabolized in the liver and induces its own metabolism. For this reason, the drug is given once a day for the first 2 weeks and twice per day thereafter.[142,143] Delavirdine is also well absorbed, with a bioavailability of 85 percent, but it requires an acidic environment and should not be given with antacids, H_2 blockers, or proton pump inhibitors. Its half-life is 6 hours, and it is metabolized in the liver.[144] The absorption of efavirenz is increased by taking it with food. However, it is recommended that the drug be administered on an empty stomach to minimize side effects. The half-life of efavirenz is 40+ hours. It is metabolized in the liver.[145,146]

INDICATIONS

- Primary or initial treatment for HIV infection.[101] As noted earlier (see Indications under Nucleoside and Nucleotide Reverse Transcriptase Inhibitors), an NNRTI is often given along with two NRTIs. Recommended regimens in nonpregnant women include efavirenz + (zidovudine or tenofovir) + (lamivudine or emtricitabine). Nevirapine may be used as an alternative to efavirenz in women with $CD4^+$ T-cell counts of less than 250 cells/mm^3 and in men with $CD4^+$ T-cell counts of less than 400 cells/mm^3.
- Management of previously treated patients experiencing treatment failure. NNRTIs may be a useful component in the treatment of patients for whom other drugs have failed. However, because of the low genetic barrier to resistance that is characteristic of this class, patients who have previously received NNRTIs may not respond.

DOSING REGIMENS

INITIATION AND MONITORING OF THERAPY See Initiation of Therapy and Monitoring of Therapy under Nucleoside and Nucleotide Reverse Transcriptase Inhibitors earlier.

RISKS AND COMPLICATIONS The most common toxicity associated with administration of nevirapine is rash (see Precautions), which can occasionally lead to Stevens-Johnson syndrome. Hepatitis may also occur with nevirapine, particularly among patients with elevated $CD4^+$ T-cell counts (see Precautions). Nevirapine decreases levels of saquinavir, indinavir, and lopinavir. Delavirdine may also produce a rash and increases levels of saquinavir, ritonavir, indinavir, nelfinavir, and amprenavir. Efavirenz often produces central nervous system side effects and decreases levels of saquinavir, indinavir, amprenavir, lopinavir, and atazanavir. However, it increases levels of ritonavir. All NNRTIs have a low genetic barrier to resistance, and adherence to the prescribed regimens is of critical importance to avoid development of resistance to this important class of drugs.

PRECAUTIONS Treatment with nevirapine must be initiated slowly to avoid high drug levels and to decrease the incidence of an erythematous, maculopapular eruption, which occurs in approximately 20 percent of patients. Observational follow-up is sufficient for mild rash. However, if the rash is severe, if extensive eruptions develop, or if mucous membranes are involved, the drug should be discontinued.

Delavirdine is generally not recommended as part of an initial treatment regimen because it has less potent antiviral activity and must be given three times daily.

Nevirapine is generally not recommended for women with $CD4^+$ T-cell counts higher than 250 cells/mm^3 or for men with $CD4^+$ T-cell counts above 400/mm^3 because of an increased risk of hepatitis in these patients.

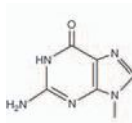
NNRTIs should not be used in combination with didanosine + tenofovir because of high rates of virologic failure and development of resistance.

Efavirenz is teratogenic in nonhuman primates and should not be administered during the first trimester of pregnancy or to women with significant childbearing potential.[147]

Protease Inhibitors

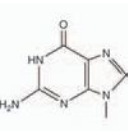
Ten protease inhibitors are currently licensed for treatment of HIV infection in the United States: saquinavir, ritonavir, indinavir, nelfinavir, amprenavir, lopinavir, fosamprenavir, atazanavir, tipranavir, and darunavir. Three of these agents—indinavir, amprenavir, and nelfinavir—are rarely used and are not discussed further.

MECHANISM OF ACTION AND DEVELOPMENT OF RESISTANCE Protease inhibitors work by inhibiting a virus-specific enzyme, protease, that is responsible for the proteolytic cleavage of viral polypeptide precursors. They thereby prevent the formation of mature virus particles. The enzyme levels required to inhibit HIV



proteases are 1000 times lower than those required to inhibit essential human proteases.[148] These compounds are active against HIV-1 and HIV-2 and may have activity against other viruses.

Protease inhibitor–resistant viruses may emerge during therapy with these agents or may be present at the time of acquisition of infection. These drug-resistant HIV strains contain a variety of amino acid substitutions, and mutations vary for different protease inhibitors. In general, as the number of mutations increases so does the degree of resistance.[149] Accumulation of mutations, especially at codons 10, 46, 54, 82, 84, and 90, may lead to multidrug resistance.[150]



PHARMACOKINETICS Oral bioavailability varies for different protease inhibitors because of differences in first-pass hepatic metabolism.[148] Saquinavir is available only as a hard capsule that has poor oral availability (4 percent). Its use in combination with low-dose ritonavir allows adequate drug levels to be reached, and saquinavir is recommended for use only concurrently with ritonavir. Lopinavir, when given alone, yields very low concentrations in plasma. When it is administered with ritonavir, however, lopinavir predose concentrations achieved in HIV-positive individuals typically exceed the concentration required for 50 percent inhibition of replication of wild-type HIV-1 by at least 50-fold.[151] The limited bioavailability of the hard gel (and first available) formulation of tipranavir led to the development of a soft capsule formulation that has better oral bioavailability,[152] and the combination of tipranavir and low-dose ritonavir is now approved for use. Ritonavir has good oral bioavailability,[153] but side effects preclude its use at full dose in most patients. Ritonavir is now used primarily at low doses to boost blood levels of other protease inhibitors. Fosamprenavir is the water-soluble, phosphate ester prodrug of the HIV-1 protease inhibitor amprenavir.[154] It provides bioavailability equivalent to that of its parent compound with a reduced pill burden and has thus largely supplanted amprenavir.[155] Atazanavir is a new azapeptide protease inhibitor with a pharmacokinetic profile that allows once-daily dosing. It may be given with or without low-dose ritonavir boosting.[156] Darunavir, when given in combination with low-dose ritonavir, has an oral bioavailability of 82 percent.[157]

Each protease inhibitor has a unique pharmacokinetic profile, but all are metabolized through the hepatic cytochrome P_{450} (CYP) system. Thus, they have important interactions with the drugs that induce, inhibit, or are themselves metabolized by CYP enzymes. Ritonavir has the most profound effect in this regard and, as noted earlier, is used frequently at a lower dose in combination with other protease inhibitors to inhibit their metabolism and thus raise their blood levels.

TABLE 232-9
Dosing Regimen for Enfuvirtide

DRUG	DOSAGE	SPECIAL CONSIDERATIONS	MAIN TOXICITIES	PRINCIPAL DRUG INTERACTIONS
Enfuvirtide (Fuzeon)	90 mg subcutaneously bid	Rotate injection sites Must be reconstituted ≤ 24 h before use	Local injection site reactions Peripheral neuropathy Insomnia Increased risk of bacterial pneumonia	None known

INDICATIONS

- Primary or initial treatment of HIV-1 and HIV-2 infections
- Management of previously treated patients who have experienced treatment failure

DOSING REGIMENS

RISKS AND COMPLICATIONS The most common side effects of the protease inhibitors include the following:

- Gastrointestinal upset
  - Nausea
  - Vomiting
  - Diarrhea
- Hepatitis
  - Occasional hepatic failure
- Dyslipidemias (except atazanavir)
- Alteration in glucose metabolism
- Fat redistribution syndrome
- Significant drug-drug interactions

In addition, tipranavir and darunavir contain sulfa moieties, and thus their use should be avoided in individuals with sulfa allergies. Atazanavir use is associated with unconjugated hyperbilirubinemia. Pruritic macular rashes have been seen in approximately 1 percent of patients treated with atazanavir.[158] Rashes have also been noted with tipranavir, darunavir, and fosamprenavir[159]; however, these occur less frequently and may be associated with concomitant use of other antiretroviral agents.

PRECAUTIONS Because most protease inhibitors are inhibitors and substrates of the CYP system, co-administration of drugs metabolized by the CYP system (and especially CYP 3A4) can lead to significant toxicity. An experienced HIV caregiver or pharmacist should be consulted before patients taking protease inhibitors start any new medications. Protease inhibitors should never be given as single agents to treat HIV infection because of the high risk of inducing resistance.

Entry Inhibitors

Entry inhibitors represent a new generation of antivirals for the treatment of HIV infection. Currently one entry inhibitor, enfuvirtide, is licensed for use in the United States.

MECHANISM OF ACTION AND RESISTANCE Enfuvirtide is a synthetic peptide of 36 amino acids that mimics a fragment of glycoprotein 41 (gp41), HR1, a portion of the envelope glycoprotein of HIV required for fusion of the viral envelope with the host cell membrane. The binding of enfuvirtide to the HR1 region of gp41 blocks the formation of a six-helix bundle structure that is critical for the fusion process.[160] Resistance to enfuvirtide involves changes in amino acids 36 to 45 within the HR1 region of gp41.[161,162]

PHARMACOKINETICS Enfuvirtide is not absorbed orally and is available clinically as a subcutaneous injection. Enfuvirtide is nearly completely absorbed from subcutaneous depot, and pharmacokinetic parameters are linear up to a dose of 180 mg.[163] Enfuvirtide is primarily eliminated via catabolism to amino acid residues. It does not influence concentrations of drugs metabolized by CYP 3A4, CYP 2D6, or *N*-acetyltransferase, and has only minimal effects on those metabolized by CYP 1A2, CYP 2E1, or CYP 2C19.[164,165]

INDICATIONS

- Management of previously treated patients who have experienced treat-

ment failure (in combination with other agents)

DOSING REGIMENS (Table 232-9)

RISKS AND COMPLICATIONS

- Local injection site reactions
  - Induration
  - Erythema
  - Nodules
  - Cysts
- Gastrointestinal upset
- Increased risk of bacterial pneumonias[166]

PRECAUTIONS Patients should be informed that injection site reactions occur in nearly all patients treated with enfuvirtide, and they should be taught how to inject the drug appropriately and how to monitor themselves for cellulitis or local infection. Because of the increased risk of pneumonia, patients should be advised to seek medical attention if they develop signs or symptoms of pneumonia.

Other Antiretroviral Drugs

There is a growing need for new antiretroviral agents that can overcome the problems of resistance, toxicities, and pill burdens of currently approved agents. Over the next 5 years a number of new antiretroviral agents are expected to be approved for use. New agents in existing classes of drugs are active against viruses resistant to currently approved drugs. Some new agents have better pharmacokinetic profiles, which allows less frequent dosing and smaller pill burdens. A number of agents seek to target new steps in the HIV replication pathway. Inhibitors of viral integrase, which specifically inhibit the strand transfer step in the integration of proviral DNA into the host genome, are currently moving into late-phase clinical trials.[167] New cell entry inhibitors targeting CC chemokine receptor 5,[168] CXC chemokine receptor 4,[169] CD4,[170] and gp120[171] are in development. Zinc finger inhibitors, which prevent packaging of viral RNA inside the nucleocapsid, also remain a focus of active investigation despite significant toxicities associated with early members of this class.[172]

CHAPTER 233

Oral Antifungal Agents

Margaret S. Lee-Bellantoni
Nellie Konnikov

Oral antifungal agents are widely and frequently used for the treatment of superficial fungal infections.[1] This chapter summarizes information on the four most widely used oral antifungals in outpatient dermatology: terbinafine, itraconazole, fluconazole, and griseofulvin.

ALLYLAMINES: TERBINAFINE

Terbinafine hydrochloride is a synthetic antimycotic agent that belongs to the family of compounds known as the *allylamines*. All allylamine derivatives possess a tertiary allylamine, a structural component crucial for antifungal activity (Fig. 233-1).[2] In vitro, the drug is primarily a fungicidal agent and highly active against dermatophytes, but less active against molds, dimorphic fungi, and various yeasts.

Mechanism of Action

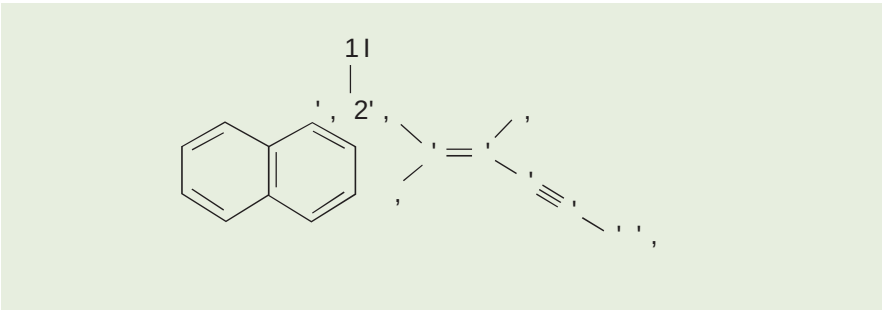
Terbinafine inhibits the enzyme squalene epoxidase in the fungal cell membrane, thereby blocking the biosynthesis of ergosterol.[3] Squalene epoxidase, a complex, microsomal non-cytochrome P_{450} enzyme, catalyzes the first enzymatic step of ergosterol synthesis: the conversion of squalene into squalene epoxide. Consequently, terbinafine causes an abnormal intracellular accumulation of squalene and a deficiency in ergosterol.[4] In vitro, accumulation of squalene accounts for the drug's fungicidal activity, while deficiency of ergosterol is associated with the drug's fungistatic activity.[4]

Pharmacology

Terbinafine is well absorbed from the gastrointestinal tract, mostly in chylomicrons. The distribution half-life is 1.5 hours, and the elimination half-life is approximately 22 hours.[5] Terbinafine is highly lipophilic and keratophilic in nature and, therefore, is widely distributed

ORAL ANTIFUNGALS AT A GLANCE

- Indicated for extensive fungal skin infections, tinea pedis, onychomycosis, and tinea capitis.
- Preventive therapy for the immunosuppressed.
- Major classes of antifungal medications used in outpatient settings are the allylamines (terbinafine), triazoles (itraconazole, fluconazole) and imidazoles (ketoconazole), griseofulvin, polyenes (nystatin, amphotericin B), and ciclopirox olamine.
- Speciation of fungal infections can be important in defining length of treatment and choosing the appropriate medication.



▲ **FIGURE 233-1** Terbinafine. (From http://www.bmb.leeds.ac.uk/mbiology/ug/ugteach/icu8/antibiotics/antifungals.html.)

upon absorption throughout skin and adipose tissue. Terbinafine is extensively biotransformed by the liver, mostly through oxidation by a very small fraction of P_{450} isoenzymes, predominantly the 2D6 isoform. More than 80 percent of the drug is excreted in urine; the rest is eliminated with feces.[6]

Indications

Terbinafine is approved by the U.S. Food and Drug Administration for the treatment of onychomycosis by dermatophytes. It also has clinically proven efficacy for various forms of tinea corporis and tinea capitis (Box 233-1).

PEDIATRIC For the treatment of tinea capitis in children, the dosage guidelines are 3 to 6 mg/kg per day.[7] Children weighing 10 to 20 kg can be given 62.5 mg/day; children weighing 20 to 40 kg can be given 125 mg/day; and those children weighing more than 40 kg can be given 250 mg/day.[8] The standard treatment course for *Trichophyton* infections is 4 weeks. A recent randomized, double-blinded study of 176 children (ages 4 to 18 years old) with predominantly *T. tonsurans* infection supports that 2- or 4-week regimens are more effective than a 1-week course.[13] In the case of tinea capitis, fungal cultures will help guide length of treatment and confirm successful cure because there is great variation in species response to any antifungal agent.[14]

Terbinafine can also be safely used in children for onychomycosis when dosed by weight as for tinea capitis.[15]

ADULT Terbinafine is indicated for the treatment of onychomycosis of the toenails and fingernails caused by dermatophytes.[16] In a study comparing continuous terbinafine with intermittent itraconazole in the treatment of toenail onychomycosis, terbinafine was significantly more effective than the pulsed itraconazole.[17] At week 72, the mycologic cure in those patients treated with a 3-month daily course of terbinafine was 75.5 percent, compared with a mycologic cure rate of 38.3 percent in those patients treated with a 3-month course of intermittent pulse therapy with itraconazole. A longer follow-up of these patients at an average of 54 months revealed 46 percent cure after continuous terbinafine versus 13 percent cure after the pulsed itraconazole[18]; similar results were found by others at 2-year follow-up.[19] Continuous terbinafine therapy was also superior to intermittent terbinafine (2-week intervals on and off the medication) for 12 weeks.[20]

In a study of 22 patients with tinea corporis and tinea cruris who used terbinafine 250 mg daily for 1 week, 100 percent clinical and mycologic clearing was observed at 6 weeks.[22] In a study of moccasin tinea pedis and tinea manuum, after a 2-week course of terbinafine, 250 mg daily, there was an 86 percent mycologic cure rate at 8 weeks.[23] Two placebo-controlled trials demonstrated that a 4- to 6-week course of terbinafine 250 mg daily is effective in the treatment of seborrheic dermatitis.[24,25] Interestingly, terbinafine is not effective orally for the treatment of tinea versicolor,[22] but twice daily application of topical terbinafine 1 percent solution, cream or gel, has been effective in randomized placebo-controlled trials.[26]

GERIATRIC Terbinafine is well tolerated by the elderly and requires no further cautions than those for the general population.[27] A recent study of 504 patients older than 65 years of age confirmed efficacy and tolerance of the standard adult regimen for onychomycosis, with no reported drug interactions.[28]

PREGNANCY CONSIDERATIONS Terbinafine is a pregnancy category B drug and should not be taken by pregnant or nursing mothers.[16]

Box 233-1

Terbinafine Treatment of Fungal Infections

- U.S. Food and Drug Administration indications
  - Onychomycosis due to dermatophytes (tinea unguium of fingernails and toenails)
- Other common uses
  - Onychomycosis due to [illegible] sp.
  - Tinea corporis and its sub-types
  - Tinea cruris
  - Tinea pedis
  - Tinea capitis
- Contraindications
  - Hypersensitivity to terbinafine or vehicle components
- Risks and precautions
  - Hepatic disease or insufficiency
  - Renal impairment
  - Pregnancy or lactation
  - History of systemic lupus erythematosus
  - Known or suspected immunodeficiency, especially neutropenia

Dosage Schedules and Formulations

Terbinafine is supplied as a 250-mg tablet and should be taken once daily for all regimens except twice-daily pulse dosing. See Table 233-1 for treatment schedules.

Initiating Therapy

Positive tests [potassium hydroxide (KOH), culture, histology] for fungal infection should be documented before initiation of oral terbinafine therapy. Pre-treatment serum transaminase tests are advised for all patients before taking terbinafine, and the drug is not recommended for patients with liver or renal disease.[23]

Monitoring Therapy

Many physicians advocate monitoring liver function after 6 weeks of therapy, although the incidence of hepatic toxicity is very low [see Complications (Adverse Effects) and Risks and Precautions].

Complications (Adverse Effects)

Because of its high selectivity, terbinafine is generally well tolerated with a low incidence of adverse side effects. The most common side effects after oral administration are of a gastrointestinal nature (3.5 percent to 5.0 percent).[31]

TABLE 233-1
Terbinafine Dosing Regimen

	ADULT	PEDIATRIC
Onychomycosis	Fingernails: 250 mg/day × 6 wk Toenails: 250 mg/day × 12 wk	3–6 mg/kg/day × 6–12 wk[a]
Tinea capitis	250 mg/day × 2–8 wk	[illegible] infections: 3–6 mg/kg/day × 2–4 wk[a] [illegible] infections: 3–6 mg/kg/day × 6–8 wk[a]
Tinea corporis, tinea cruris	250 mg/day × 1–2 wk	3–6 mg/kg/day × 1–2 wk
Tinea pedis (moccasin)	250 mg/day × 2 wk	[b]
Seborrheic dermatitis	250 mg/day × 4–6 wk	[b]

[a]Pediatric weight-based dosing: 62.5 mg/day (10–20 kg), 125 mg/day (20–40 kg), 250 mg/day (> 40 kg).
Note: Higher cure rates obtained with 4.5 mg/kg/day or greater.
[b]No large studies.

Risks and Precautions

Terbinafine should be prescribed with caution in patients with hepatic disease or history of hepatic toxicity with other medications. Furthermore, there is insufficient data to recommend its use in patients with renal impairment. Because terbinafine rarely causes a lupus-like rash and neutropenia, patients with known systemic lupus erythematosus or immunodeficiency also may not be good candidates for this medication.[16]

Drug Interactions

Terbinafine is not contraindicated with any specific drug. However, terbinafine is metabolized by cytochrome P_{450} (CYP) enzymes. Plasma clearance of terbinafine is increased by the P_{450}-inducer rifampin and decreased by the P_{450}-inhibitor cimetidine.[40] Terbinafine is also reported to decrease cyclosporine levels by increasing cyclosporine clearance.[23,41]

TRIAZOLES

Both itraconazole and fluconazole are triazole antimycotic agents sharing a common structural moiety—a triazole ring—not found in azoles of the imidazole family.

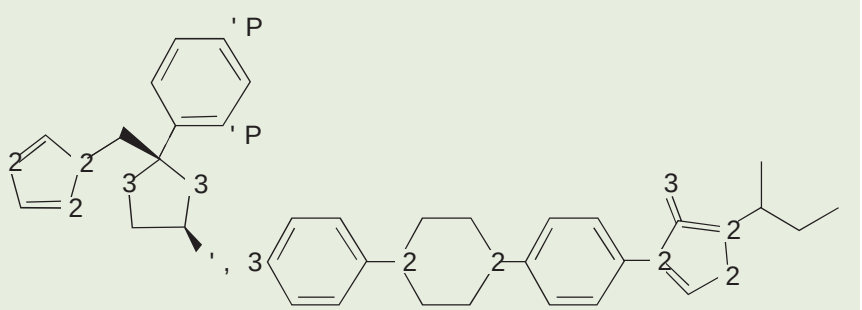
Itraconazole

Itraconazole (Fig. 233-2) is a highly lipophilic compound[45] that has a wide spectrum of activity. In vitro, it is fungistatic and effective against dermatophytes, yeast, molds, and dimorphic and dematiaceous fungi.[46–48]

MECHANISM OF ACTION Itraconazole inhibits 14-α-demethylase, a microsomal cytochrome P_{450} enzyme, in the fungal membrane.[49] 14-α-Demethylase is necessary for the conversion of lanosterol to ergosterol, which is the principal structural component of the fungal cell membrane.[47] Consequently, the accumulation of 14-α-methylsterols leads to the impairment of membrane permeability and membrane-bound enzyme activity and to the arrest of fungal cell growth.

PHARMACOLOGY The serum concentration of itraconazole is influenced by several parameters, including food and gastric acidity.[50,51] Itraconazole is extensively metabolized, primarily by the CYP 3A4 isoenzyme system to more than 30 metabolites. Hydroxyitraconazole is the main metabolite. Approximately 54 percent of the metabolized drug is excreted in the feces, and 34 percent is excreted in the urine. Absorption of the standard tablet formulation is decreased in patients with acquired immunodeficiency syndrome as a result of gastric hypochlorhydria.[52] A new hydroxypropyl-β-cyclodextrin oral solution formulation is better absorbed in a fasting state than with food,[53] appropriate for patients who cannot ingest large amounts of food or have high gastric pH. Young children, especially those less than 5 years of age, have lower serum levels than adults and usually require twice daily dosing.[54]

INDICATIONS Itraconazole has the broadest efficacy compared to other commonly-prescribed antifungals.[48] Thus, it is a first-line therapy for infections due to *Candida* and other nondermatophyte species (Box 233-2).



▲ **FIGURE 233-2** Itraconazole. (From http://www.bmb.leeds.ac.uk/mbiology/ug/ugteach/icu8/antibiotics/antifungals.html.)

Box 233-2

Itraconazole Treatment of Fungal Infections

- U.S. Food and Drug Administration indications
  - Onychomycosis due to dermatophytes
  - Continuous therapy for fingernails and toenails
  - Pulsed therapy for fingernails
  - Systemic mycoses (blastomycosis, histoplasmosis, aspergillosis)
  - Fungal empiric therapy in febrile neutropenia (oral solution)
  - Oropharyngeal candidiasis (oral solution)
  - Esophageal candidiasis (oral solution)
- Other common uses
  - Onychomycosis due to [illegible] sp.
  - Tinea corporis and its sub-types
  - Tinea cruris
  - Tinea pedis
  - Tinea capitis
- Contraindications
  - Hypersensitivity to itraconazole or vehicle components
  - Co-administration with cisapride, midazolam, pimozide, quinidine, dofetilide, triazolam, 3-hydroxy-3-methylglutaryl coenzyme A–reductase inhibitors (cytochrome P_{450} 3A4 metabolized drugs)
- Risks and precautions
  - Hypersensitivity to other azoles
  - Hepatic disease or insufficiency
  - History or risk of congestive heart failure, ischemic and valvular disease (negative inotropic effect observed)
  - Chronic obstructive pulmonary disease
  - Renal disease
  - Pregnancy or lactation
  - Drug interactions with cytochrome P_{450} 3A4 metabolized drugs

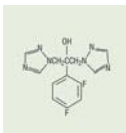


TABLE 233-2
Itraconazole Dosing Regimen

	ADULT	PEDIATRIC
Onychomycosis	Fingernails: 200 mg bid × 1 wk/mo × 2 pulses Toenails: 200 mg/day × 12 wk SV 200 mg bid × 1 wk/mo × 3 pulses	Fingernails: 5 mg/kg/day × 1 wk/mo × 2 pulses[a] Toenails: 5 mg/kg/day × 1 wk/mo pulsed × 3 pulses
Tinea capitis	250 mg/day × 2–8 wk	[illegible] infections: 5 mg/kg/day × 2–4 wk Microsporum infections: 5 mg/kg/day × 4–8 wk
Tinea corporis, tinea cruris, tinea pedis	200 mg bid × 1 wk SV 100–200 mg/day × 2–4 wk	Dose by weight × 1–4 wk
Oropharyngeal candidiasis	Swish and swallow solution 100–200 mg/day	Swish and swallow solution by weight
Pityriasis versicolor	200 mg/day × 5–7 days, prevent recurrence with 200 mg bid once/mo	[b]

[a]Pediatric weight-based dosing: 100 mg/day (15–30 kg), 100 mg/day alternating with 200 mg/day (30–40 kg), 200+ mg/day (> 50 kg).
[b]No large studies.

Pediatric. Itraconazole can be used to treat tinea capitis in children. It is more often prescribed in the capsule formulation with food or acidic beverages such as colas because the cyclodextrin in the liquid form of itraconazole causes more gastrointestinal side effects such as diarrhea and also due to reports of neoplasms associated with high doses in murine and rat models.[55] Nevertheless, for children who cannot swallow capsules or take capsules with food, the solution has a pleasant taste and is considered to be safe.[56]

The oral solution is a good option for oropharyngeal or esophageal candidiasis in children, even in fluconazole-resistant infections.[54]

Adult. Itraconazole has been approved for the treatment of onychomycosis caused by dermatophytes[55] and is effective as continuous or pulse therapy. A 2-month course of itraconazole pulse therapy is necessary for fingernail onychomycosis, while toenail onychomycosis requires a 3-month course. A single course consists of 200 mg twice daily for 1 week per month. Itraconazole pulse therapy is at least equal in efficacy, if not superior, in the treatment of toenail onychomycosis when compared to continuous itraconazole therapy.[60]

Geriatric. Itraconazole (pulse) therapy is effective and safe in the elderly and only requires caution in the setting of comorbidities and drug interactions [see Complications (Adverse Effects) below].[27]

Pregnancy Considerations. Itraconazole is a pregnancy category C drug, and therefore, is not recommended during pregnancy or while nursing because it is excreted in human milk.[55]

DOSAGE SCHEDULES AND FORMULATIONS Itraconazole is supplied in 100 mg capsules, a 10 mg/mL oral solution, and an intravenous solution. Capsules should be taken with a full meal to ensure maximum absorption.[55] Dosage schedules are discussed in Pediatric, Adult, Geriatric, and Pregnancy Considerations above and in Table 233-2.

INITIATING THERAPY Positive tests (KOH, culture, histology) for fungal infection should be documented before initiation of oral itraconazole therapy. Baseline evaluation of hepatic function is recommended in patients with pre-existing liver disease, or if lengthy treatment is anticipated.[55]

MONITORING THERAPY Hepatic function monitoring is indicated through therapy only for those patients with pre-existing liver disease or those with a history of hepatic toxicity with other medications.[55,63] When itraconazole must be administered with medications it is known to compete with for hepatic enzymes, appropriate monitoring for drug levels or toxic effects of these medications is indicated (see Drug Interactions below).

COMPLICATIONS (ADVERSE EFFECTS) The most common reported side effects associated with itraconazole therapy are of a gastrointestinal nature.[64] Instances of hepatic injury and, rarely, fulminant hepatotoxicity are associated with the administration of itraconazole. There are also rare reports of congestive heart failure and pulmonary edema. When administered intravenously to dogs and healthy human volunteers, negative inotropic effects were noted.[66]

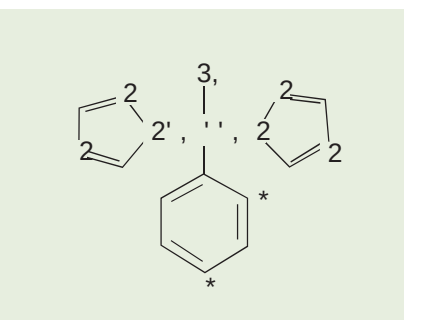
RISKS AND PRECAUTIONS Administration of itraconazole to patients with a history of heart failure is contraindicated, and it is not recommended for patients with a history of liver disease.[55] There are also several significant drug interactions to be aware of.

DRUG INTERACTIONS Itraconazole inhibits its 14-α-demethylase, a fungal P_{450} enzyme[49] and a member of the same group of enzymes present in the human liver that is responsible for the metabolism of many drugs. Itraconazole specifically inhibits CYP 3A4, and consequently, may increase plasma concentrations of drugs metabolized by this pathway. Because itraconazole is itself metabolized by CYP 3A4, any inducers or inhibitors may respectively decrease or elevate itraconazole levels. Absorption of itraconazole may be decreased by the concomitant administration of antacids, H_2-blockers, and proton pump inhibitors.[3]

Fluconazole

Fluconazole (Fig. 233-3) is fungistatic in vitro[46] and is effective against many yeasts (with the exception of *Candida krusei*) and dermatophytes.[68]

MECHANISM OF ACTION Fluconazole, like itraconazole, inhibits 14-α-demethylase, a microsomal cytochrome P_{450} enzyme, in the fungal membrane.[49]



▲ **FIGURE 233-3** Fluconazole. (From http://www.bmb.leeds.ac.uk/mbiology/ug/ugteach/icu8/antibiotics/antifungals.html.)

PHARMACOLOGY The pharmacokinetic parameters of fluconazole are similar for both intravenous and oral administration.[68] Extensive absorption (> 90 percent) of the triazole appears to be comparable in both postprandial and fasting states and not dependent on stomach acidity.[51,69] Fluconazole exhibits a long half-life of 25 to 30 hours, and a steady-state level is reached after 7 days of once-daily administrations. Fluconazole is only weakly bound to plasma proteins, with about 90 percent of the drug circulating free in the plasma. The drug is resistant to hepatic metabolism, and hence, approximately 80 percent of fluconazole is excreted unchanged in urine, with 2 percent in feces and approximately 11 percent as metabolites in urine.[70] The ability to diffuse substantially into the cerebrospinal fluid distinguishes this compound from many other antimycotic agents.[71] The levels of fluconazole in cerebrospinal fluid, saliva, vaginal tissue, sputum, skin, and blister fluids are reported to be comparable with or to exceed simultaneous plasma concentrations.[72] Altered fluconazole pharmacokinetics, including decreased plasma clearance, are detected in patients with cirrhosis[73] and renal impairment.[74] In children over 3 months of age, fluconazole clearance is more rapid than in adults.[54]

INDICATIONS Fluconazole is established as a first-line therapy for mucocutaneous candidiasis. It is useful for its convenient once-weekly dosing schedule (Box 233-3).

Pediatric. Fluconazole has been used successfully to treat tinea capitis at 6 mg/kg/day for 20 days for *T. tonsurans* infection,[75] and at 5 mg/kg/day for 30 days.[57] A course as brief as 2 weeks may be equally effective as terbinafine and itraconazole for *Trichophyton* infections.[58] When *Mycoplasma canis* is present, a longer treatment course is recommended.[59]

Adult. Vaginal candidiasis can conveniently and safely be treated with a single 150-mg dose of fluconazole, or weekly for 6 months or longer in the case of recurrent vulvovaginal candidiasis.[76]

For the treatment of tinea pedis, weekly doses of fluconazole 150 mg has been given for a period of 3 to 4 weeks,[77] with a 75 percent mycologic cure rate at 4 weeks. Fluconazole at a dose of 150 mg weekly for 24 weeks is significantly inferior to terbinafine 250 mg daily for 12 weeks in the treatment of onychomycosis.[78] Pityriasis versicolor can be treated with a single 400-mg dose of fluconazole.[79] In a recent small, open-label randomized study of pityriasis versicolor treatment comparing a single 400-mg dose of fluconazole with a single 400-mg dose of itraconazole, fluconazole led to greater cure than itraconazole (65 percent vs. 20 percent, respectively) with fewer relapses noted (35 percent vs. 60 percent, respectively) at an 8-week follow-up assessment by KOH and culture tests.[80]

Box 233-3

Fluconazole Treatment of Fungal Infections

- U.S. Food and Drug Administration indications
  - Vaginal candidiasis
  - Oropharyngeal and esophageal candidiasis
  - Cryptococcal meningitis
  - Prophylaxis against candidiasis in bone marrow transplant patients
- Other common uses
  - Onychomycosis due to dermatophyte and [illegible] sp.
  - Cutaneous and chronic mucocutaneous candidiasis
  - Tinea corporis and its sub-types
  - Tinea cruris
  - Tinea pedis
  - Tinea capitis
  - Pityriasis versicolor
  - Sporotrichosis
- Contraindications
  - Hypersensitivity to fluconazole or vehicle components
  - Co-administration with terfenadine or cisapride
- Risks and precautions
  - Hypersensitivity to other azoles
  - Proarrhythmic cardiac conditions
  - Renal impairment (dose adjustment required)
  - Pregnancy or lactation

Geriatric. Fluconazole is well tolerated in the elderly[81]; however, dose modification is required in elderly patients with renal impairment.[72]

Pregnancy Considerations. Fluconazole is a pregnancy category C drug and is not recommended in pregnant or nursing mothers.[82]

DOSAGE SCHEDULES AND FORMULATIONS Fluconazole is available in 50-mg, 100-mg, 150-mg, and 200-mg tablets; in 10-mg/mL and 40-mg/mL oral solutions; and in an intravenous form. It is approved for use in children age 6 months and older, although not specifically for tinea capitis.

INITIATING THERAPY Positive tests (KOH, culture, histology) for fungal infection should be documented before initiation of oral fluconazole. There are no specific recommendations for baseline laboratories before starting fluconazole therapy.

MONITORING THERAPY There are no specific monitoring recommendations other than drug levels in renal disease. Because fluconazole is prescribed as a one-time dose or once weekly, there is little need for laboratory monitoring other than that indicated by side effects.

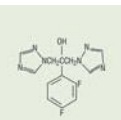
COMPLICATIONS (ADVERSE EFFECTS) The most common recognized side effects of fluconazole therapy are gastrointestinal.[83] There are rare reports of fatal hepatotoxicity associated with fluconazole, but most studies in both humans and rats have shown less hepatotoxicity when compared to other azoles.[85] There are even fewer reports of torsades de pointes, with or without concomitant medications or underlying cardiac arrhythmias.[86]

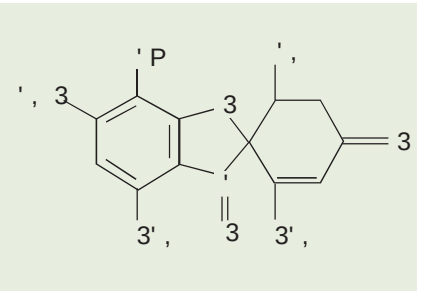
RISKS AND PRECAUTIONS To prevent serious hepatic and cardiac toxicity, one should exercise caution when prescribing to patients with multiple co-morbidities, immunosuppression or pre-existing liver or cardiac disease; close monitoring may be helpful in these patients.

DRUG INTERACTIONS In humans, fluconazole inhibits both CYP 3A4 and CYP 2C9 in a dose-dependent manner,[3] and consequently may increase plasma concentrations of drugs metabolized by these pathways. Therefore, a number of drugs that are metabolized by CYP 3A4 or CYP 2C9 are contraindicated or require close monitoring. Co-administration of terfenadine or cisapride with fluconazole is contraindicated.[82]

IMIDAZOLES: KETOCONAZOLE

Ketoconazole was introduced in the 1970s as the first effective oral azole antifungal. However, because of the drug's many adverse reactions and the availability of safer, efficacious medications, it is not used as a first-line agent for the treatment of dermatophyte infections or *Candida*.





▲ **FIGURE 233-4** Griseofulvin. (From http://www.bmb.leeds.ac.uk/mbiology/ug/ugteach/icu8/antibiotics/antifungals.html.)

MISCELLANEOUS: GRISEOFULVIN

Griseofulvin (Fig. 233-4) has been used since 1958 for the treatment of dermatophyte infections.[59] Griseofulvin is not effective for candidiasis, deep fungal infections, or pityriasis versicolor.

MECHANISM OF ACTION Griseofulvin is fungistatic in vitro,[59] and has a narrow spectrum of antimycotic activity. It disrupts microtubule mitotic spindle formation, thereby causing mitotic arrest at the metaphase stage.[87]

PHARMACOLOGY The absorption of griseofulvin is enhanced by several factors, including concurrent intake of a fatty meal and a smaller particle size formulation. Griseofulvin is mainly metabolized by the liver before excretion.[88]

INDICATIONS As one of the early antifungal medications, griseofulvin has been U.S. Food and Drug Administration approved for several dermatophyte infections. However, because of its limited spectrum of coverage compared to other agents and the lengthy courses required, griseofulvin is not used as a first-line therapy for fungal infections other than tinea capitis.

Pediatric. Griseofulvin is still currently the drug of choice for the treatment of tinea capitis, but this may change as studies continue to validate shorter effective courses with the newer antifungal agents.[46] Griseofulvin is recommended at a dosage higher than that suggested by the manufacturers at 20 to 25 mg/kg/day (microsize), or 15 to 20 mg/kg/day (ultramicrosize) to complete a minimum course of 6 to 8 weeks for *T. tonsurans*.[57] However, longer treatment with griseofulvin is recommended for *M. canis* infections.[57]

Adult. Although griseofulvin is indicated for the treatment of fingernail and toenail onychomycosis, therapy is prolonged with low cure and high relapse rates, requiring approximately 6 months for the treatment of fingernails and 12 months for toenails.[87]

Geriatric. The safety of griseofulvin therapy in the elderly has not been formally evaluated in trials. However, studies including elderly patients have not specifically reported an increased incidence of adverse effects among this age group.[89,90]

Pregnancy Considerations. Griseofulvin is a pregnancy category C drug. Because griseofulvin interferes with chromosomal distribution during cell division, males should wait at least 6 months after completing griseofulvin therapy before fathering a child.[91]

DOSAGE SCHEDULES AND FORMULATIONS Griseofulvin is formulated as ultramicrosize tablets in 125-mg, 165-mg, 250-mg, and 330-mg doses.[92] It is also formulated as griseofulvin microsize and is available as 250-mg and 500-mg tablets and in a 125-mg/5-mL suspension.[91] To maximize absorption, it should be taken with fatty foods. The manufacturers' recommended dosing is 5 to 10 mg/kg/day (ultramicrosize) or 10 to 20 mg/kg/day (microsize).

INITIATING THERAPY Positive tests (KOH, culture, histology) for fungal infection should be documented before initiation of therapy. There are no specific recommendations for baseline laboratories before starting griseofulvin therapy.

MONITORING THERAPY There are no specific monitoring recommendations.

COMPLICATIONS (ADVERSE EFFECTS) The most common side effects are related to the gastrointestinal tract and the central nervous system, such as headache, dizziness, and insomnia.[87] The drug is reported to precipitate lupus erythematosus and, rarely, severe skin reactions, including Stevens-Johnson and angioedema. As a result of impaired porphyrin metabolism, griseofulvin therapy is associated with photoallergic reactions. Griseofulvin is contraindicated in patients with porphyria and hepatocellular failure.[92]

RISKS AND PRECAUTIONS Patients should be warned about potential photosensitivity induced by griseofulvin and the possibility of lupus erythematosus or a lupus-like syndrome.[93]

DRUG INTERACTIONS Griseofulvin induces CYP3A4, leading to lower plasma levels of drugs metabolized by this pathway.[3] Two important examples are decreased anticoagulation by warfarin and potential decreased effectiveness of oral contraceptive pills.

ORAL ANTIFUNGALS IN THE IMMUNOCOMPROMISED

Oral antifungal therapy is increasingly important for the treatment and prevention of infection in immunocompromised individuals, even in an outpatient setting. For example, as more patients survive organ transplantation,[94,95] more fungal infections are likely to be observed. In one recent report of 100 consecutive liver transplant patients seen by a dermatology clinic, fungal infections were much more common (19 percent of total skin infections) than bacterial (5 percent) or viral (2 percent).[96]

Candidiasis and aspergillosis are the most common opportunistic fungal infections in many immunocompromised populations. The extensive use of fluconazole prophylactically in patients with acquired immunodeficiency syndrome, transplants, hematologic malignancies, and other causes of immunosuppression has led to decreased susceptibility of some candidal infections to fluconazole.[97] One should keep in mind, however, that itraconazole solution has more drug interactions and potential compliance issues due to nausea and diarrhea.

New antifungal medications with activity against resistant species and excellent safety profiles continue to be developed. The new class of antifungals, echinocandins, provide both benefits by specifically targeting fungal cell wall β-1,3-D-glucan synthesis (absent in mammalian cells). However, poor oral bioavailability currently limits these drugs to intravenous formulations.[100]

EVIDENCE-BASED MEDICINE CONSIDERATIONS

Interpretation of competing studies continues to be difficult because endpoints have not been uniform. Such endpoints may be mycologic cure, clinical cure, complete cure, and effective treatment. Criticisms of these studies include the fact that many were open label, leading to investigator bias.[101] Many studies fail to take into account the physiology of nail growth.[19] Toenails can take up to 18 months to grow out fully. Therefore, stud-

ies at 48 to 52 weeks might not accurately reflect clinical or mycologic cure. Several studies of the treatment of tinea pedis did not always specify the type of tinea pedis, despite known variations amongst forms of tinea pedis in response rate to therapy. Studies of moccasin tinea pedis are preferred as successful treatment usually indicates that the antifungal drug will be effective in the milder forms of tinea pedis as well as tinea corporis and tinea cruris.[101] Finally, the efficacy of antifungal agents depends on the sensitivity of the dermatophyte. For example, in the treatment of tinea capitis, if the causative organism is *M. canis*, longer treatments may be needed than if the organism is *T. tonsurans*. [45] In North America, most tinea capitis is caused by *T. tonsurans*, while surveys in the United Kingdom demonstrate that the predominant dermatophyte is *M. canis*.[59] Consequently, trials assessing the efficacy of a drug may be influenced by the culprit dermatophyte and indirectly by the location of the study.

CHAPTER 234

Immunosuppressive and Immunomodulatory Drugs

Carlos H. Nousari
Grant J. Anhalt

There has been significant progress in the search for selective immunomodulation; the most significant advance in immunotherapy has been the reduction in systemic glucocorticoids exposure along with early or concomitant introduction of immunosuppressive and immunomodulatory adjuvants. Unlike immunomodulators, immunosuppressants are characterized by (1) a low therapeutic index (narrow window between the toxic and the therapeutic range) and (2) intra- and interindividual variation of the pharmacokinetics of these agents. These obstacles are usually overcome by precise drug dosing (ideal/lean body weight and body surface area) as well as close monitoring of drug levels (parent and metabolite serum peak and trough levels) and organ toxicity.

The main goals in immunotherapy therapy are "safety and effectiveness," which currently are accomplished by the use of "combination therapy."[1,2] The ideal immunotherapy combination is the one that combines drugs that have different mechanisms of action and different toxicity profiles. Thus, an additive or synergistic therapeutic effect will be obtained along with a significant reduction in dose-dependent side effects.

A comprehensive knowledge of the pathophysiology of the treating disease as well as of the pharmacokinetics and pharmacodynamics concepts is crucial for delineating the most effective and safest therapeutic regimens for autoimmune and inflammatory skin disorders (see eFig. 234-0.1 in on-line edition; Fig. 234-1).

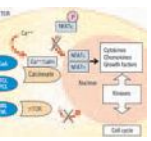
MACROLACTAM DRUGS

Macrolactam drugs are immunomodulators derived from microorganism fermentation products that include calcineurin inhibitors (CnIs) [e.g., cyclosporine, tacrolimus (TCL), and pimecrolimus] and mammalian target of rapamycin inhibitors (mTORIs) [e.g., sirolimus (SRL) and everolimus (EVL)]. Macrolactams are versatile immunomodulators that selectively suppress T-cell response and have synergistic therapeutic effects when they are combined with virtually any other immunosuppressive drug.[1,2]

Calcineurin Inhibitors

MECHANISM OF ACTION CnIs inhibit T-cell stimulation initiated by several pathways, of which the T-cell receptor (TCR) CD3 is the best understood.[3] Mechanisms involving B-7 and CD28/cytotoxic T lymphocyte antigen-4, and other co-stimulatory pathways seem not to be affected by cyclosporine A (CsA) or other CnIs. The high-affinity receptor for CsA is a 17-kd immunophilin called *cyclophilin A* (*CyPA*). The other CnIs (TCL and pimecrolimus) bind a structurally unrelated, different immunophilin called *macrophilin-12* also known as *FK-506 binding protein-12* (*FKBP-12*). The drug-immunophilin complex binds to calcineurin (Cn), a serine/threonine protease composed of two subunits: CnA and CnB. CnA constitutes the catalytic unit possessing binding sites for CnB and calmodulin. Cn activity strictly correlates with interleukin 2 (IL-2) production via CD3 activation. Cn is also involved in the induction of apoptosis and degranulation of cytotoxic T lymphocytes. Experimental data show that the CsA, TCL, and pimecrolimus/Cn complex inhibits the nuclear translocation of the nuclear factor of activated T cells c molecule by blocking its dephosphorylation. This is thought to be the key step by which these drugs uncouple TCR activation from IL-2 transcription. TCL is 10- to

IMMUNOSUPPRESSIVE AND IMMUNOMODULATORY DRUGS AT A GLANCE



- The main goals in immunotherapy are safety and effectiveness.
- Unlike immunomodulators, immunosuppressive drugs are all characterized by a narrow therapeutic window requiring precise dosing and close side-effect monitoring.
- The highest level of safety and effectiveness in immunotherapy therapy is currently accomplished by the use of combined regimens.
- An additive or synergistic combined immunotherapeutic regimen allows significant reduction of dose-dependent drug side effects maintaining or improving the effectiveness, respectively.
- A comprehensive knowledge of the pathophysiology of the treating disease as well as of the pharmacokinetics and pharmacodynamics concepts is crucial for delineating the most effective and safest therapeutic regimens.

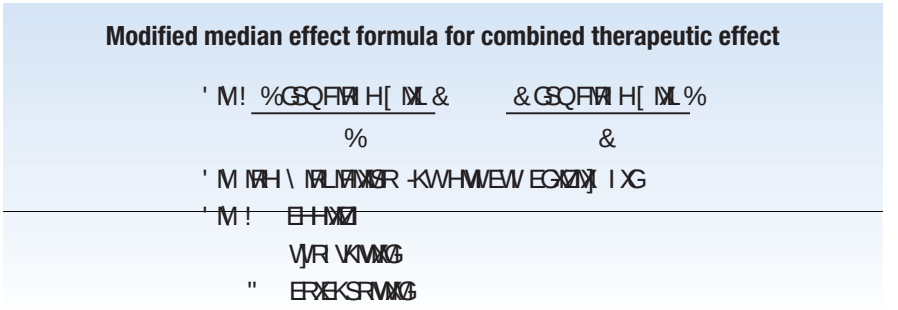
100-fold more potent than CsA in vitro in the inhibition of Cn activity.

In summary, CsA inhibits the T-cell activation mediated by antigen, but it does not inhibit the early phases of lymphocyte signal transduction occurring after antigen-mediated activation. The immunomodulatory effects of these drugs are intricate and subject to constant discoveries. A simplified explanation of the mechanism of action of these drugs is presented in the following sections and is illustrated in Fig. 234-2.

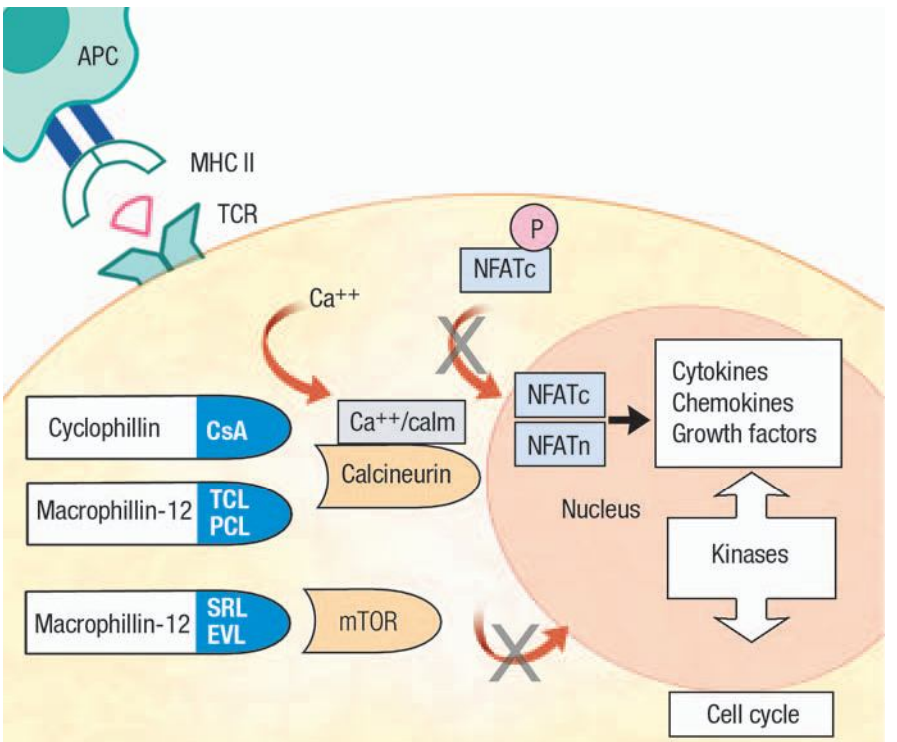
CYCLOSPORINE A CsA is a hydrophobic lipophilic undecapeptide extracted from fungi.

Pharmacokinetics. The microemulsion-based formulation of CsA has an improved bioavailability giving the drug more predictable absorption.[3,4]

Modified median effect formula for combined therapeutic effect



▲ **FIGURE 234-1** A modified, median-effect formula is widely used in organ transplant, which helps in finding the therapeutic windows of immunosuppressive drugs as well as the synergistic, additive, or antagonistic effect of a postulated drug combination. Igs = immunoglobulins. (From Chou TC, Talalay P: Quantitative analysis of dose-effect relationships: The combined effects of multiple drugs or enzyme inhibitors. %GZ) R'] QI 6I KY22:27, 1984.)



▲ **FIGURE 234-2** This diagram outlines the key mechanisms by which calcineurin (Cn) inhibitors and mammalian target of rapamycin (mTOR) inhibitors inhibit T-cell activation triggered by presentation of antigen via the T-cell receptor (TCR). The first step in antigen presentation involves presentation of a peptide that is bound within the peptide-binding groove of the major histocompatibility complex (MHC) class II molecule. This complex is then presented to the TCR. This causes transmembrane signaling that increases intracellular calcium concentrations. The liberated calcium, bound to calmodulin, interacts with Cn, a calcium-dependent serine/threonine phosphatase that dephosphorylates nuclear factor of activated T cells (shown here as NFATc), and this causes NFAT to translocate to the nucleus. There it binds to other nuclear components of NFAT (shown here as NFATn). This complex regulates the transcription of many cytokine genes, shown in the diagram. Cyclosporine (CsA), tacrolimus (TCL), and pimecrolimus (PCL) diffuse freely into the cytoplasm of T cells and bind with their respective immunophilins. This drug/immunophilin complex binds to Cn and blocks its ability to dephosphorylate NFAT, and thereby inhibits the production of cytokines, chemokines, and growth factors [interleukin 2 (IL-2), IL-3, IL-4, tumor necrosis factor-α, interferon-γ, granulocyte-macrophage colony-stimulating factor, etc.] that would normally be induced after T-cell activation via the TCR. Sirolimus (SRL) has a more complex intracellular mechanism of action. Although SRL and everolimus (EVL) bind macrophilin-12 (also known as */ &4), the immunophilin of TCL and PCL, its mechanism of action does not appear to be mediated by Cn inhibition. mTOR inhibitors block cell kinases that would have a direct effect on the cell cycle by also an indirect effect in chemokine, cytokine, and growth factor synthesis. APC = antigen-presenting cell.

CsA can also be administered intravenously as a 50 mg/mL solution made up in an ethanol-polyoxyethylated castor oil mixture. The accumulation of CsA in erythrocytes and leukocytes is the reason that whole-blood monitoring of CsA levels is much more accurate than measurement of plasma levels. Peak levels occur from 1.3 to 4.0 hours after oral administration. After gaining access to the circulation, CsA distributes widely and has a large apparent volume of distribution (13 L/kg). CsA is metabolized into greater than 30 cyclic, partly active metabolites by the liver cytochrome P_{450} 3A enzyme (CYP 3A).[5,6] Thus, drugs that compete for binding to CYP 3A will increase CsA levels, and drugs that induce P_{450} will accelerate metabolism and decrease blood levels. Certain foods rich in bioflavonoids, especially grapefruit, seem to increase the drug's bioavailability through an interaction with cytochromes. Its elimination half-life is 6 to 12 hours in the absence of severe hepatic disease, and biliary excretion accounts for more than 90 percent of its elimination. CsA solution does have some penetration of mucosal surfaces, but this is not true of cornified epithelium. Intralesional injections of CsA do provide some local effects in psoriasis, but they are not widely used.

Indications

- Psoriasis
  - Moderate to severe psoriasis
  - Part of combined therapy
  - Failure of conventional treatment
- Graft-versus-host disease
  - Prophylaxis
- Pyoderma gangrenosum
  - Moderate to severe disease
  - Part of combined therapy
  - Failure of other treatments
- Paraneoplastic pemphigus
  - Part of combined therapy, namely in lichenoid forms
- Lichen planus
  - Mucosal and/or cutaneous forms
  - Moderate to severe cases
  - Solo or part of combined therapy
- Atopic dermatitis
  - Moderate to severe cases
- Behçet disease
  - Ocular and mucocutaneous forms
  - Moderate to severe cases
- Dermatomyositis
  - Moderate to severe forms
- Alopecia areata
- Recurrent aphthous stomatitis
- Epidermolysis bullosa acquisita

Dosing Regimen. (Table 234-1)

TABLE 234-1
Cyclosporine A Dosing Regimen

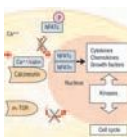
	ORAL	INTRAVENOUS
Adults	2.5–5.0 mg/kg/day	2–3 mg/kg/day
Children	5–7 mg/kg/day	3–5 mg/kg/day

Initiating Therapy. Doses higher than 5 mg/kg/day are not advisable. The U.S. Food and Drug Administration has approved CsA for psoriasis in doses up to 4 mg/kg/day, with a recommended starting dose of 2.5 mg/kg/day. Dosage increases should be performed after 4 weeks of therapy, and dose reductions are permitted at any time. Dosage increases should not exceed 0.5 to 1.0 mg/kg/day at 2- to 4-week intervals. Intravenous CsA formulation can be infused slowly over a period of 2 to 6 hours at about one-third of the usual oral dose, or about 2 to 3 mg/kg per day.[7]

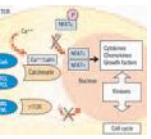
Monitoring Therapy. With psoriatic patients going into remission, defined as a reduction in the psoriasis area and severity index of greater than 75 percent, the CsA dose should be down-titrated at 4-week intervals. The two most common assays for trough levels are high-performance liquid chromatography (HPLC) and radioimmunoassay are performed in EDTA-containing whole blood. The recommended range is 200 to 400 ng/mL. Children have comparable bioavailability of orally ingested CsA, but have a higher renal drug clearance rate (11.8 mL/min per kg vs. 5.7 mL/min per kg in adults), and a correspondingly shorter blood level half-life (7.3 hours vs. 10.7 hours in adults). Children may therefore require somewhat higher dosages and more frequent administration to achieve comparable trough levels to adults.

Risks and Precautions. Serum creatinine levels should be carefully monitored during CsA therapy. If creatinine levels increase more than 30 percent above baseline, the dosage should be reduced for 1 to 2 weeks. If, after that time, the creatinine levels decrease below the 30 percent elevation mark, continuation at the lower dose is advisable. In cases where the creatinine remains elevated by more than 30 percent, discontinuation of CsA is recommended until the creatinine returns to levels within 10 percent of pre-treatment levels. More accurate studies monitoring the glomerular filtration rate clearance are used in individualized cases. From a practical standpoint, adequate monitoring of CsA dosage can be achieved by the avoidance of CsA doses higher than 5 mg/kg/day, evaluation of clinical response, and vigilance for signs of toxicity. This requires a detailed physical examination, including blood pressure monitoring with threshold concern triggered by a persistent diastolic blood pressure above 90 mm Hg, a complete history with emphasis on concomitant drug ingestion and medical conditions that may potentiate CsA toxicity, and laboratory evaluations for complete blood count, creatinine and blood urea nitrogen, uric acid, liver enzymes, serum electrolytes and magnesium, and a urinalysis. In patients receiving long-term CsA therapy (> 6 months), the serum creatinine and its clearance may not be a reliable predictor of altered renal function, and potentially irreversible chronic cyclosporine nephrotoxicity may ensue. In such circumstances, more reliable studies for the evaluation of renal function may be indicated.

Complications. **RENAL FUNCTION, LIVER, AND NEUROLOGIC.** Overall, one in four patients taking CsA develops clinical and laboratory evidence of altered renal function, including hypertension. Two types of CsA-induced nephrotoxicity are encountered in dermatologic patients. The first type usually starts within 2 to 3 weeks after drug initiation, and it is usually associated with high CsA blood levels. In this toxicity, there is an insidious decrease in glomerular filtration rate along with hypertension, and tubular dysfunction in association with a complete recovery of renal function upon dose-lowering or discontinuing therapy. The second type is likely a result of cumulative sub-clinical chronic renal toxicity. This may occur in the absence of any detectable elevation of creatinine or blood pressure. Histologic changes include interstitial fibrosis, tubular atrophy, and some degree of vasculopathy. Although renal function can improve somewhat after discontinuation of the drug, this type of toxicity is generally irreversible. In psoriatic patients receiving 5 mg/kg/day CsA, elevation of serum creatinine may persist



for more than 4 months after discontinuation of the drug. Several mediators, including endothelin-1, angiotensin II, osteopontin, and transforming growth factor-β1, have been implicated in the pathogenesis of CsA-associated nephrotoxicity and hypertension. Calcium channel antagonists exert beneficial effects on CsA-induced hypertension and nephrotoxicity, presumably through the inhibition of endothelin-1. Other drugs, including angiotensin converting inhibitors (enalapril, lisinopril, etc.) and angiotensin receptor blockers (losartan, valsartan, etc.), are also effective mainly when used in combination with other antihypertensive drugs. New drugs, such as endothelin A receptor blockers (bosentan, darusentan, etc.) and renin inhibitors (aliskiren), appear to be promising for CsA-treated patients.[8–10] Diuretics and nephrotoxic drugs should be used with caution in CsA-treated patients. Another uncommon adverse renal complication is the development of thrombotic microangiopathy/hemolytic-uremic syndrome,[11,12] especially in allogenic bone marrow transplant patients receiving CsA for acute graft-versus-host disease. Hypomagnesemia and hyperkalemia or hypokalemia are not uncommonly encountered.



Nausea, vomiting, anorexia, and diarrhea commonly occur with the use of CsA. Elevations of liver enzymes greater than 100 percent over baseline should be managed by reduction of the CsA dose by 25 percent weekly, until enzyme levels normalize.

Headache is a common complaint, especially in patients with a history of migraines. It tends to resolve spontaneously as therapy continues. CsA-induced seizures appear to be associated with hypomagnesemia and concomitant use of high doses of systemic corticosteroids. Thus, serum magnesium levels should be always monitored and kept above the lower normal range in CsA-treated patients. Cortical blindness, lethargy, confusion, seizures, hemiplegia, tremors, and paresthesias have also been described in patients receiving CsA.[8]

There is evidence of impaired fibrinolysis and endothelial damage and proliferation associated with CsA. Hypercoagulability seems to contribute to the progression of atherosclerosis and glomerular damage in CsA-treated patients. Significant cytopenias have rarely been reported with the use of CsA.

Hypercholesterolemia, elevation of low-density lipoproteins, and hypertriglyceridemia may be seen with CsA.

CANCER. CsA-treated transplant recipients have a relative risk for all skin cancers of 6.8 versus 2.2 to 5.5 in patients receiving other immunosuppressive therapies. CsA-treated dermatologic patients also have a higher risk of skin cancers, including squamous cell carcinomas, basal cell carcinomas, human papilloma virus–associated anogenital carcinoma, and Kaposi sarcoma. The high incidence of squamous cell carcinoma in psoriatic patients treated with CsA could be biased by previous exposures to psoralen and ultraviolet A light or ultraviolet B. Approximately 25 percent of non-visceral Kaposi sarcomas can be expected to undergo complete or partial remission following cessation or reduction of immunosuppressive therapy. Epstein-Barr virus–associated post-transplant lymphoproliferative disorder (PTLD) is quite rare in dermatologic patients. PTLD frequently usually fails to respond to chemotherapy, but it may regress spontaneously after reduction and/or cessation of immunosuppression. The incidence of lymphoma in CsA-treated dermatologic patients appears to be less than 0.2 percent. The incidence of lymphoma in transplant patients receiving CsA alone or in combination with corticosteroids is less than 1 percent, whereas for those receiving CsA in conjunction with other immunosuppressive drugs is as high as 8 percent. In contrast to the high mortality rate attributed to lymphomas arising in immunosuppressed patients, lymphomas developing in CsA-treated patients seem to carry a better prognosis despite of having a shorter latency period seems.[13–15] In rheumatoid arthritis patients treated with CsA, there was no increase in malignancies in comparison with a matched control group of patients with rheumatoid arthritis who were not treated with CsA. Other neoplasms, including melanoma, are also reported in CsA-treated patients, although their true incidence is unknown.

OTHER ADVERSE EFFECTS. Hypertrichosis occurs in virtually all patients on long-term CsA therapy. It is not limited to androgen-dependent, hair-bearing areas, and shows no tendency to spontaneous remission. Gingival hypertrophy is reported in up to 70 percent of CsA-treated patients; it is more common in children, individuals with poor oral hygiene and concomitant use of calcium channel drugs. Improvement of this gingival complication with topical or systemic azithromycin and metronidazole can be seen. An acneiform eruption, indistinguishable from that seen in steroid-induced acne, is frequently reported. A disseminated comedonal or cystic acneiform eruption can also occur. These side effects can appear at any time during CsA therapy, although they are more commonly described at the time of initiation of CsA therapy. Keratosis pilaris, sebaceous hyperplasia, warts, and epidermal inclusion cysts occur in up to one-third of CsA-treated patients.

Osteoporosis seems to result from the CsA's action on osteoblasts and osteoclasts, and by altering lymphokine release. CsA can induce hyperuricemia in up to 15 percent of patients, and it is also an indicator of early CsA-induced nephrotoxicity. Myopathy has been reported in transplant patients receiving high doses of CsA, and thus, cation should be used with the concomitant use of statins.

PREGNANCY. CsA does not seem to be mutagenic or teratogenic, although there is a high incidence of preterm newborns, fetal growth retardation, abortions, preeclampsia, and hypertension in mothers taking CsA, and these occurrences are magnified in transplant patients. There are no reports of neonatal complications in children born to fathers receiving CsA. Adequate contraceptive measures are recommended in women of childbearing potential. CsA crosses the placenta and is excreted in breast milk. CsA-treated transplant patients seem to have a relative risk for infectious, life-threatening complications that is much lower than that seen in patients receiving azathioprine and prednisolone. However, increased vigilance for infectious complications is recommended in CsA-treated patients.

TACROLIMUS

TCL, a CnI formerly known as *FK506*, is a macrolactam drug first isolated from *Streptomyces tsukubaensis*.

Mechanism of Action. The postulated mechanisms of action of TCL are similar, if not identical, to the ones described for CsA (see Macrolactam Drugs).[16]

Pharmacokinetics. TCL can be administered orally, topically, and intravenously. The pharmacokinetics of systemic TCL are characterized by a two-compartment model with a rapid initial drop and a long elimination half-life of 12 to 21 hours. TCL is metabolized in the liver with less than 1 percent of the drug excreted intact. TCL has not proved to be more effective than CsA, but it appears

TABLE 234-2
Tacrolimus Dosing Regimen

	ORAL	INTRAVENOUS
Adults	150–200 μg/kg/day	25–50 μg/kg/day
Children	200–300 μg/kg/day	50–100 μg/kg/day

to have a better bioavailability. The topical formulations have a concentration of 0.3 percent and 0.1 percent in an ointment vehicle, and for more detailed information, see Chap. 221.

Dosing Regimen. (Table 234-2)

Initiating Therapy. The dosage of systemic TCL should be reduced in the presence of hepatic dysfunction by 10 percent to 30 percent of the standard dosing.

Monitoring Therapy. There is a good correlation between enzyme-linked immunosorbent assay and HPLC mass spectrometry measurements in monitoring of whole blood concentrations of TCL. Enzyme-linked immunosorbent assays may also detect metabolites of the drug, and thus, caution should be taken in patients with liver diseases or with concomitant use of CyP4503A-binding drugs. Blood levels of 5 to 15 ng/mL are recommended.

Risks and Precautions. The risks and precautions are quite similar to the ones applied for CsA. However, neurotoxicities and glucose intolerance are somewhat higher than with CsA use, and thus, close monitoring of magnesium and glucose serum levels and, if indicated based on personal or family history, glucose tolerance tests are strongly recommended. The risk for PTLD seems to be higher in children with hepatic transplants who received both TCL and anti-OKT3, but it has not been definitively proved in dermatologic patients or in different clinical scenarios. Dose reduction and close monitoring of TCL levels by HPLC mass spectrometry in patients with liver diseases are strongly recommended. A less graft-versus-leukemia effect in comparison with the one seen with CsA is observed in bone marrow transplant patients. A great deal of concern has been raised regarding the potential risk of lymphoproliferative diseases with this drug, which led to a highly controversial placement of a black box warning by the U.S. Food and Drug Administration with the topical formulation (see Chap. 221).

Complications. Mucocutaneous and metabolic side effects seem to be less frequent with the use of TCL. However, nephrotoxicity seems to be comparable to that seen with the use of CsA. The rest of the side effects are comparable with those seen with CsA use.

Indications

- Psoriasis
- Pyoderma gangrenosum
- Atopic dermatitis
- Graft-verus-host disease
  - Prophylaxis
  - Therapy
- Lupus erythematosus
  - Systemic
  - Chronic cutaneous

Systemic TCL can be used virtually in any inflammatory and autoimmune skin disease in which systemic CsA has proved effective.[17–21] For topical use of TCL, see Chap. 221.

PIMECROLIMUS Pimecrolimus, also known as *ASM 981*, is a derivative of the parent compound ascomycin originally isolated from the fermentation products of *S. hygroscopicus* var. *ascomyceticus*. Pimecrolimus has a similar mechanism of action as that of other CnIs. Pimecrolimus is formulated in vehicle cream at concentrations of 0.2 percent, 0.6 percent, and 1.0 percent (see Chap. 221).

Mammalian Target of Rapamycin Inhibitors

MECHANISM OF ACTION SRL and its derivatives EVL and temsirolimus are most widely known as *mTORIs*. Although mTORIs bind to FKBP-12 (macrophilin-12), this drug-immunophilin complex inhibits gene transcription through a complex mechanism that is independent from the one involving Cn.

TABLE 234-3
Sirolimus Dosing Regimen

	DAILY ORAL DOSE
Adult—African and Asian descents	3–10 mg
Adult—Caucasians	0.5–3.0 mg
Children	1.5 mg/m^2

PHARMACOKINETICS African and Asian descent patients require a higher initial and maintenance dose of SRL than Caucasians. EVL bears a stable 2-hydroxyethyl chain substitution at position 40 on the SRL structure, which has given a greater polarity than SRL, improving the pharmacokinetic and particularly its oral bioavailability. Oral EVL is absorbed rapidly and reaches peak concentration after 1.5 hours. In adults, EVL pharmacokinetic characteristics do not differ according to age, weight, or sex, but body weight-adjusted dosages are necessary in children.[25–26] The target trough concentration of EVL should range between 3 and 15 ng/dL. SRL topical formulation (2.2 percent and 8.0 percent) has been use in psoriasis patients (see Chap. 221).

INDICATIONS

- Graft-versus-host disease
  - Prophylaxis
  - Refractory chronic
- Psoriasis
  - Severe
  - Solo therapy
  - Combination therapy with Cn inhibitors
  - mTORIs have a potential use in any inflammatory dermatosis in which CnIs play a therapeutic role.

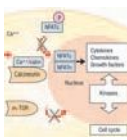
DOSING REGIMEN (Tables 234-3 and 234-4)

INITIATING THERAPY As mentioned in Table 234-3, due to ethnic differences, the SRL recommended oral loading dose is 6 mg and oral maintenance dose is 2 mg per day for Caucasian patients, and the oral loading dose is 10 mg and oral maintenance dose is 5 mg per day for African Americans. Asians also appears to require higher doses of this drug. EVL starting dose are the same regardless of sex and race. The usual dosing for adults is 0.75 to 1.5 mg bid and for children 0.8 to 1.2 mg/m^2.

MONITORING THERAPY Due to significant intra- and interindividual variability, mea-

TABLE 234-4
Everolimus Dosing Regimen

	DAILY ORAL DOSE
Adults	0.8–1.2 mg/m^2
Children	0.75–1.5 mg/bid



suring trough levels is critical with the use of mTORIs. Through levels for SRL and EVL are 5 to 20 ng/dL and 3 to 15 ng/mL, respectively. Complete blood cell count, electrolytes, liver function test, and a lipid profile, along with a comprehensive clinical examination with periodic blood pressure measurement, are mandatory.

RISKS AND PRECAUTIONS Concomitant use of antimetabolite drugs, including mycophenolate mofetil (MMF) and azathioprine in patients with mTORIs of upper normal or higher trough blood levels (e.g., SRL: equal or higher than 20 ng/dL or EVL: equal or higher than 5 ng/mL), raises the risk of cytopenias, namely thrombocytopenia. Concomitant use of CnIs, namely TCL, may increase the risk of thrombotic microangiopathy/hemolytic uremic syndrome, and thus, monitoring of blood cell count, dyslipidemia, electrolyte abnormalities, edema, and increase of liver function tests are also associated with high trough levels of these drugs. Patients with extensive psoriasis treated with SRL should be monitored closely for capillary leak syndrome, a rare complication reported only in one series.[27]

COMPLICATIONS Cytopenias, namely thrombocytopenia, hypertriglyceridemia, hypercholesterolemia, arthralgias, edema, and impaired wound healing, have been frequently associated with the use of mTORIs. Occurrence of cytomegalovirus appears to be lower that observed with the use of CnIs. No gingival hyperplasia has been observed with SRL. Tremor or any other neurologic complications are not frequent. Hypertension and malignancies are significantly reduced in comparison with the use of CnIs. This is most likely related to the endothelial, mesangial antiproliferative and antineoplastic properties of mTORIs.

MYCOPHENOLATE MOFETIL

MMF is an ethyl ester of its active metabolite, mycophenolic acid (MPA) a product of several *Penicillium* species.

Mechanism of Action

MMF is the reformulated product of MPA, but with enhanced bioavailability. MPA inhibits the type II isoform of inosine monophosphate dehydrogenase in the de novo pathway of purine synthesis. Lymphocytes are quite susceptible to this drug effect, because they minimally use the hypoxanthine–guanine phosphoribosyl transferase salvage pathway for purine synthesis. Other less understood mechanisms have also been reported.

Pharmacokinetics

The drug is rapidly absorbed after oral administration, and antacids and cholestyramine may decrease its absorption. Approximately 5 percent of the drug is bound to albumin. It is nearly completely metabolized by glucuronyl transferase, and more than 90 percent of the drug is eliminated by the kidneys. The MMF glucuronide metabolite, which is increased in renal failure, increases MMF clearance by competing for its binding sites on albumin. MMF pharmacokinetics seems not to be affected by the concomitant administration of CsA. As with many other immunosuppressive agents, doses up to 20 percent higher may be required for children due to a physiologic increased liver metabolism. A new oral formulation of MPA, mycophenolate sodium enteric coating (MP-EC), has been proved to be as effective as MMF at conversion dose as follows: 250 mg of MMF = 180 mg of MP-EC and 500 mg of MMF = 360 mg of MP-EC. This new formulation is less expensive and appears to have less gastrointestinal side effects.

Indications

- Atopic dermatitis
- Autoimmune blister diseases
- Chronic actinic dermatitis
- Connective tissue diseases
- Graft-versus-host disease
- Lichen planus
- Psoriasis
- Pyoderma gangrenosum
- Vasculitic syndromes

Dosing Regimen (Table 234-5)

TABLE 234-5
Mycophenolate Mofetil Dosing Regimen

	Daily Oral Dose
Cytotoxic T-cell mediated diseases	25–35 mg/kg
Antibody-mediated diseases	35–55 mg/kg

Note: 180 mg of mycophenolate sodium enteric coating is the equivalent of 250 mg of mycophenolate mofetil; 360 mg of mycophenolate sodium enteric coating is the equivalent of 500 mg of mycophenolate mofetil.[27,28]

Initiating Therapy

MMF is commonly used in synergistic and safe combination with CsA and glucocorticoids.

MMF is commonly used with systemic corticosteroids as adjuvant therapy. The full therapeutic effect of MMF or MP-EC, namely on antibody-mediated diseases, shouldn't be expected until 2 or 3 months after therapy initiation. The therapeutic and toxic profiles of MMF have led this drug to be the substitute of azathioprine.

Monitoring Therapy

Measurement of serum levels of MPA shows inconsistent predictive value to monitor effectiveness and toxicity in MMF-treated patients. Complete cell count and a liver function test are recommended to be monitored on a monthly basis.

Risks and Precautions

Gastrointestinal side effects, occasionally with intractable diarrhea, namely in elderly patients, are common, but in the vast majority of the cases they disappear with continuation of therapy, dividing the total daily dose (e.g. three or four times a day), and taking the drug with food. Increased risk of herpes zoster virus re-activation is rather common, namely in elderly patients and patients with autoimmune blistering disease (author's personal observation). Significant cytopenias could be expected when combined with mTORIs. Dose reduction should be made for patients with liver diseases.

Complications

Expected toxicities include nausea, upset stomach, vomiting, and diarrhea. There is no increase in nephrotoxicity, hepatotoxicity, hypertension, or neurotoxicity when MMF is used in conjunction with CsA and corticosteroids. The hematologic and gastrointestinal side effects are dose dependent and usually clinically insignificant. An increased incidence of lymphoproliferative diseases and lymphoma is reported with its use, as well as predisposition for infectious complication, usually non–life-threatening.[30–38]

Other antimetabolite and immunosuppressive agents are discussed in Chap. 228.

CHAPTER 235

Immunobiologicals, Cytokines, and Growth Factors in Dermatology

Stephen Richardson
Joel Gelfand

The cytokines, growth factors, antibody-based agents, and fusion proteins discussed in this chapter are listed in Table 235-1. Fig. 235-1 illustrates the targets of some of these biologics in T-cell activation, and Fig. 235-2 indicates where in cutaneous inflammation these and other biologics intervene.

TABLE 235-1
Immunobiologicals, Cytokines, and Growth Factors

Recombinant cytokines	
Interferon-α and interferon-γ	Enhance cell-mediated cytotoxicity against viral disease and malignancy via promotion of major histocompatibility complex expression and suppression of T helper 2 cytokine production
Recombinant ILs and growth factors	
IL-2	Maintains helper T-cell populations Enhances natural killer cell cytotoxicity and lymphokine activated cell activity
IL-1 receptor antagonist	Blocks the interaction between IL-1 and its receptor Suppresses IL-1–mediated inflammatory responses (e.g., leukocyte recruitment, osteoclast activation)
Granulocyte-macrophage colony-stimulating factor	Promotes the proliferation and differentiation of myeloid precursors
Platelet-derived growth factor	Promotes wound healing via angiogenic activity and proliferative effects on fibroblasts and smooth muscle cells
Antibody-based therapeutics	
Anti-TNF-α	Infliximab: chimeric monoclonal antibody; neutralizes both membrane-bound and soluble TNF-α Adalimumab: human monoclonal antibody; neutralizes both membrane-bound and soluble TNF-α
Anti–LFA-1	Efalizumab: humanized monoclonal antibody; interferes with lymphocyte activation, cytotoxicity, and trafficking to the skin
Anti-CD20	Rituximab: chimeric monoclonal antibody; promotes a reduction in $CD20^+$ cells (B cells)
Fusion proteins	
Alefacept	Human immunoglobulin G1 Fc region fused to LFA-3 extracellular domain; interferes with T-cell activation by blocking the interaction between LFA-3 and CD2
Etanercept	Human immunoglobulin G1 Fc region fused to TNF type II receptor domain; neutralizes soluble TNF-α
Denileukin diftitox	Diphtheria-toxin component fused to IL-2; promotes apoptosis of T cells expressing the high affinity IL-2 receptor, CD25

IL = interleukin; LFA = leukocyte function–associated antigen; TNF = tumor necrosis factor.

RECOMBINANT CYTOKINES AND GROWTH FACTORS

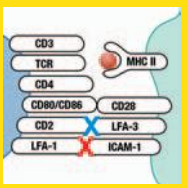
Cytokines are low molecular weight polypeptides that exhibit paracrine and/or autocrine activity in the mediation of immune responses. These hormone-like substances may serve as growth factors via the induction of immune cell proliferation. They may also influence the production of other cytokines and the behavior of multiple cell types that express the appropriate receptors. Over the past two decades, recombinant cytokines have proven to be of great use for the management of conditions in which immunologic aberrancies may exist or in which some clinical benefit might be derived from augmentation or suppression of the host immune response. In particular, the clinical and histologic manifestations of psoriasis have been attributed to the effects of T helper 1 (Th1) cytokine production. Thus, the development of compounds designed to regulate both immune cell activation and pro-inflammatory cytokine production has become a focus in therapeutic drug development for psoriasis.

Recombinant Interferons

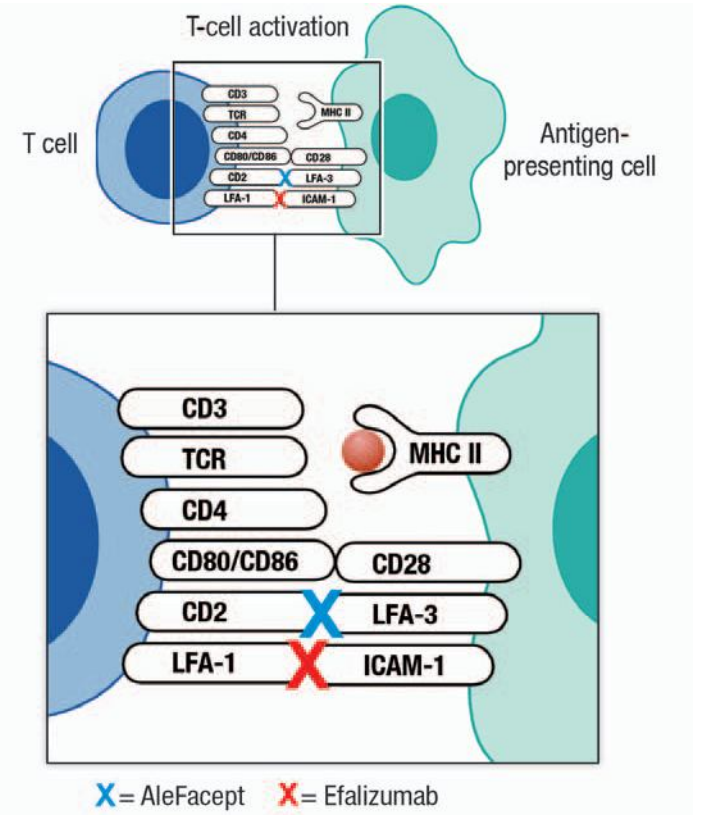
INTERFERON-α Interferon-α (IFN-α) is a type I IFN produced by plasmacytoid

IMMUNOBIOLOGICALS, CYTOKINES, AND GROWTH FACTORS

AT A GLANCE



- The development of drugs that modulate immune cell function through stimulatory or inhibitory mechanisms has shown great promise in the treatment of conditions with underlying immune abnormalities. These drugs are often referred to as the [illegible] and are defined as compounds engineered from living organisms that induce or alter immune responses by interacting with specific biologic targets.
- Biologic agents available for the treatment of cutaneous disease range from recombinant cytokines and growth factors to monoclonal antibodies and fusion proteins.
- Targeting the immune system with biologics may result in an increased risk of infections and malignancies.



▲ **FIGURE 235-1** Immunobiologicals may modify immune responses via inhibition of T-cell activation. Efalizumab blocks interactions between leukocyte function–associated antigen 1 (LFA-1) and intercellular adhesion molecule 1 (ICAM-1), whereas alefacept interferes with interactions between CD2 and LFA-3. MHC II = major histocompatability complex II; TCR = T-cell receptor.

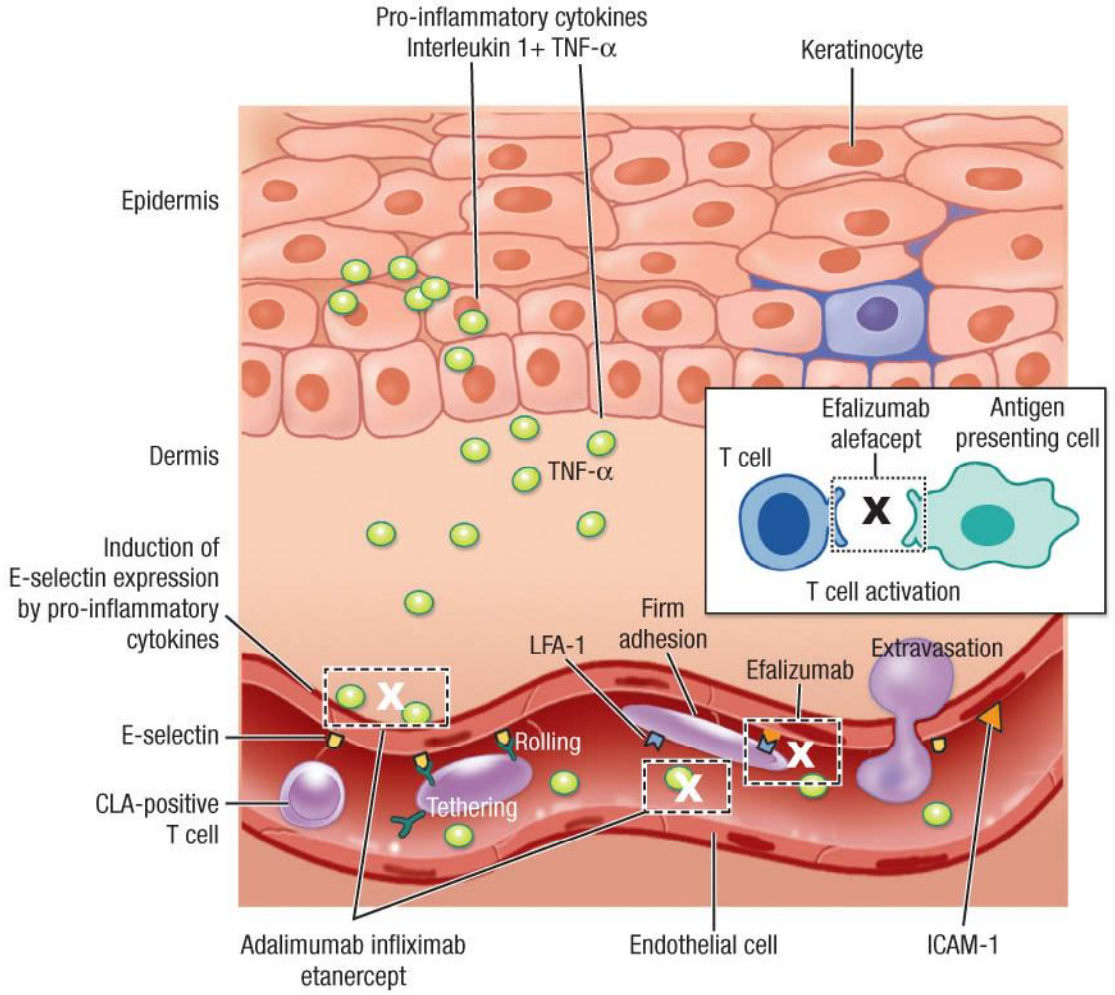
dendritic cells. It enhances cell-mediated cytotoxicity against viral disease and malignancy by increasing major histocompatibility complex I expression by antigen-presenting cells, stimulating natural killer cell activity, promoting the development of Th1 cells, and suppressing the production of Th2 cytokines.[1,2]

Recombinant IFN-α may be administered as a subcutaneous or intramuscular injection and has been used for a broad range of dermatologic conditions that include cutaneous T-cell lymphoma (CTCL), melanoma, non-melanoma skin cancer, Kaposi sarcoma, Behçet disease, hemangiomas, condyloma acuminatum, verruca vulgaris, and keloids.[3] A pegylated form (containing polyethylene glycol) of this compound is currently available, which has a longer half-life and increased patient tolerability.[2] Before the availability of pegylated IFN-α, treatment was typically administered three times per week with dosing dependent upon the condition being treated and patient response to therapy. Pegylated IFN-α may be administered once weekly with a steady state plasma level of drug achieved within 5 to 9 weeks.[4]

There is extensive experience using IFN-α in the treatment of CTCL. Objective clinical responses have been noted among 50 percent to 75 percent of CTCL patients treated with a variety of IFN-α dosing regimens.[5] Typically, it is administered subcutaneously (SC) at a starting dose of 1.5 million units three to five times per week. The first clinical trial using IFN-α for the treatment of CTCL was conducted by Bunn et al., in which patients with refractory, advanced-stage CTCL were treated with high dose (50×10^6 U/m^2) intramuscular injections three times a week. At the maximum tolerated dose, 10 percent of patients achieved a complete response, and 45 percent had an objective response.[6] Olsen et al. have since reported significant clinical responses in greater than 60 percent of CTCL patients (stage Ia–IVa) treated with IFN-α.[5] When combined with other immunomodulatory therapies, high clinical responses have been achieved among patients with Sézary syndrome.[7]

The most common side effect associated with IFN-α therapy is flu-like symptoms characterized by fever, sweats, chills, myalgias, and arthralgias. These symptoms typically resolve over the first 10 days of therapy and can be managed with acetaminophen. Patients may also experience injection site reactions. Other associated side effects include fatigue, depression, weight loss, photosensitivity, peripheral neuropathy, psychosis, hypothyroidism, and sexual dysfunction.[2,8] Laboratory abnormalities include elevated hepatic transaminases and leukopenia. Liver function tests and a complete blood count should be evaluated every 1 to 2 weeks on initiation of therapy or with any increase in dosing.[2]

IFN-α is contraindicated for use in patients with a known hypersensitivity to the drug or any of its components. Relative contraindications include a history of cardiovascular disease, renal disease, hepatic disease, central nervous system disorders, and/or pre-existing mental health disturbances. IFN-α is a pregnancy category C medication with unknown safety during lactation. IFN-α may also



▲ **FIGURE 235-2** Cutaneous inflammation results in the production of inflammatory cytokines that induce keratinocyte proliferation and increase expression of molecules such as E-selectin. Immunobiologicals may interfere with immune cell trafficking by binding to specific cell surface receptors, deplete target cell populations through direct binding to cell surface proteins, suppress cytokine activity through the action of cytokine targeting compounds, and alter immune responses via the activity of recombinant cytokines with inhibitory or pro-inflammatory properties. The cellular interactions and cytokines targeted by several of the immunobiological agents discussed in this chapter are depicted. CLA = cutaneous lymphocyte–associated antigen; ICAM-1 = intercellular adhesion molecule 1; LFA-1 = leukocyte function–associated antigen 1; TNF-α = tumor necrosis factor-α.

exacerbate autoimmune diseases such as sarcoidosis, and therefore, it should be used with caution in individuals with a history of autoimmune disease.[9,10]

INTERFERON-γ IFN-γ is a cytokine produced by Th1 lymphocytes. Similar to IFN-α, it enhances cell-mediated cytotoxicity and suppress Th2 cytokine production. IFN-γ has also been shown to enhance major histocompatibility complex 2 expression and interleukin 12 (IL-12) production by antigen-presenting cells. In the dermatologic setting, it is reported to exhibit clinical efficacy in the management of chronic granulomatous disease and CTCL.

Children with chronic granulomatous disease treated with IFN-γ exhibited a significant reduction in the frequency of infections and associated hospitalizations.[11] Studies regarding the use of IFN-γ in the treatment of CTCL are limited. Partial clinical responses have been reported among patients treated with IFN-γ during all stages of disease.[12] Such responses may be attributed, in part, to the ability of IFN-γ to suppress the production of Th2 cytokines by malignant cells.[13] Thus, IFN-γ may offer a meaningful alternative to patients who may not tolerate or respond to IFN-α therapy secondary to the formation of neutralizing antibodies, or cognitive dysfunction and fatigue—which are more frequently associated with IFN-α therapy.[14]

IFN-γ is administered via intravenous, intramuscular, and/or subcutaneous routes. Dosing regimens vary, depending upon the condition being treated. The recommended treatment for children with chronic granulomatous disease involving greater than 0.5 m^2 body surface area is 50 μg/m^2 three times a week for life.[15] We have used IFN-γ doses ranging from 50 to 100 μg three times a week for the treatment of adult CTCL patients.[2]

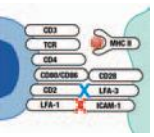
Adverse effects associated with IFN-γ are similar to those reported for IFN-α and include flu-like symptoms, elevated hepatic transaminases, leukopenia, and thrombocytopenia. IFN-γ is a pregnancy category C medication with unknown safety during lactation. Its contraindications are similar to those reported for IFN-α.

Recombinant Interleukins and Growth Factors

INTERLEUKIN 2 IL-2 is a Th1 cytokine with anti-tumor activity produced by $CD4^+$ lymphocytes in response to activation by antigen-presenting cells. IL-2 has been shown to promote the prolif-

eration and maintenance of helper T-cell populations. In addition, it has also been shown to enhance both natural killer (NK) cell cytotoxicity and lymphokine-activated cell activity.[16] In the dermatologic setting, recombinant human IL-2 has been used for the treatment of melanoma and CTCL.

Several studies have reported durable clinical responses among melanoma patients treated with IL-2 therapy. This finding led to the U.S. Food and Drug Administration (FDA) approval of this medication for the treatment of patients with metastatic disease. In early studies, high dose intravenous IL-2 therapy (600,000 to 720,000 IU/kg) led to a 15 percent to 20 percent overall response among melanoma patients, with 4 percent to 6 percent achieving a complete clinical response.[17–19]



Adverse effects associated with infused IL-2 include fever, chills, hypotension, thrombocytopenia, vascular leak syndrome, pulmonary edema, cardiac arrhythmias, renal compromise, and exfoliative erythroderma.[2,3] IL-2 is contraindicated for use in patients with a known hypersensitivity to the drug or any of its components. It is also contraindicated for patients with a history of an abnormal thallium stress test, abnormal pulmonary function tests, or organ allograft transplantation. IL-2 is a pregnancy category C medication with unknown safety during lactation.

INTERLEUKIN 1 RECEPTOR ANTAGONIST

GRANULOCYTE-MACROPHAGE COLONY-STIMULATING FACTOR Granulocyte-macrophage colony-stimulating factor (GM-CSF) is a growth factor that induces the proliferation of myeloid precursors and is involved in the proliferation, differentiation, and migration of dendritic cells.[21] In the dermatologic setting, GM-CSF has been reported to exhibit efficacy as a wound-healing agent by promoting the proliferation of keratinocytes in the setting of ulcerated, diseased skin in specific case studies.[22,23] It has also been used as an antitumor agent in the treatment of melanoma and CTCL.

Regression of in-transit melanoma and cutaneous metastases have been reported with the administration of intralesional recombinant GM-CSF.[24,25] A phase II trial in which GM-CSF was administered to postsurgical, clinically disease-free, stage III or IV melanoma patients reported enhanced survival among treated patients compared to matched historical controls.[26]

Recombinant human GM-CSF has also been used as adjuvant therapy in the treatment of patients with Sézary syndrome. Clinical improvement was reported in a patient treated with an aerosolized form of the medicine.[27] In addition, we have used GM-CSF in combination with other immune-modulating therapies for the treatment of Sézary syndrome, leading to enhanced clinical responses.[7] GM-CSF been shown to induce the differentiation and proliferation of antigen-presenting cells[28] and may contribute toward disease improvement in Sézary syndrome through its ability to partially restore antigen-presenting cell populations, which have been shown to be reduced in Sézary syndrome patients.

Recombinant human GM-CSF dosing for the treatment of dermatologic disease has not been standardized. Associated side effects include fatigue, myalgia, injection site reactions, and generalized cutaneous reactions. GM-CSF is contraindicated for use in patients with a known hypersensitivity to the drug or any of its components. Administration of this drug in combination with chemotherapy or radiotherapy should be avoided. GM-CSF is a pregnancy category C medication with unknown safety during lactation.

RECOMBINANT HUMAN PLATELET-DERIVED GROWTH FACTOR Platelet-derived growth factor (PDGF) is a peptide produced by platelets, macrophages, neutrophils, and smooth muscle cells that has proven to be of clinical benefit for the management of chronic wounds. It consists of two polypeptide chains (A and B) that form dimers linked by disulfide bonds. The PDGF-BB homodimer has been shown to promote granulation tissue formation, wound angiogenesis, re-epithelialization, and the proliferation of fibroblasts and smooth muscle cells in the cutaneous microenvironment. It is currently the only growth factor approved by the FDA for the treatment of diabetic foot ulcers.

Several randomized control studies have reported the efficacy of PDGF-BB for the treatment of pressure ulcers and lower extremity ulcers in diabetic patients. A phase II randomized, double-blind clinical trial reported a greater than 50 percent decrease in the size of ulcers treated with topical recombinant PDGF at doses of 100 or 300 μg/mL compared to a less than 20 percent decrease in the placebo group.[29] A recent phase III study also reported significant efficacy of PDGF-BB in the time required to achieve complete wound closure for the treatment of chronic diabetic neuropathic ulcers of the lower extremities.[30] This multicenter, double-blind, placebo controlled study reported a 43 percent increase in the incidence of wound closure, and a 32 percent reduction in the time required to achieve complete wound closure compared to patients receiving a placebo gel.

PDGF-BB (100 μg/g) is distributed as a topical gel that should be applied daily and refrigerated when not in use. Studies addressing the safety of recombinant human PDGF-BB found no increased risk for cardiovascular, respiratory, musculoskeletal, or central nervous system disorders among patients with lower extremity diabetic neuropathic ulcers treated with topical PDGF-BB compared to patients treated with placebo or general ulcer care.[31] Patients receiving PDGF-BB therapy did not develop neutralizing antibodies to the drug, nor did they exhibit an increase in mortality rate relative to placebo. Cutaneous eruptions have been reported but are uncommon.

Recombinant PDGF-BB is contraindicated for use in patients with a known hypersensitivity to the drug or any of its components. It also should not be applied to sites affected by cutaneous neoplastic disease. PDGF-BB is a pregnancy category C medication with unknown safety during lactation.

ANTIBODY-BASED THERAPIES

Through their ability to regulate immune responses via the activation and/or suppression of pathways that mediate inflammation, immunologic tolerance, and antitumor immunity, cytokines serve as useful biologic targets for recombinant antibody therapy. Recombinant antibody-based therapeutics have also been developed to target specific cell surface receptors. These compounds have the ability to deplete distinct cell populations and/or inhibit signal transduction cascades associated with the targeted molecule. Antibody-based pharmacologics can be identified by their suffix, which denotes the structural nature of the compound (*-ximab*: chimeric monoclonal antibody [a hybrid antibody consisting of human and murine antibody components], *-zumab*: humanized monoclonal antibody, *-umab*: human monoclonal antibody, *-cept*: antibody fusion protein that mimics immunoglobulin).

Antibodies Against Cytokines

ANTI-TUMOR NECROSIS FACTOR-α Tumor necrosis factor-α (TNF-α) is a cytokine that has been linked to the pathogenesis of psoriasis and other inflammatory conditions, including psoriatic arthritis, rheumatoid arthritis, and inflammatory bowel disease. It is produced by multiple cell types in the skin (keratinocytes, Langerhans cells, and dermal mast cells),[32] which are believed to contribute to the pathogenesis of inflammatory dermatoses. TNF triggers its effects by binding to its p55 and p75 receptors expressed primarily on the surface of keratinocytes, neutrophils, endothelial cells, and fibroblasts. In combination with other proinflammatory cytokines, it is believed to be involved in the recruitment of immune cells to the cutaneous microenvironment.[33] TNF may also contribute to both the inhibition of keratinocyte apoptosis and the induction of keratinocyte proliferation in psoriasis.[34,35]

Psoriasis is a chronic inflammatory condition of the skin that affects more than 2 percent of the adult population[36] (see Chap. 18). Elevated levels of TNF-α have been detected in the cutaneous lesions of psoriasis patients.[37] Recent murine studies report a role for TNF-α in the activation and proliferation of lymphocytes that induce psoriatic lesions.[38] Elevated TNF-α levels have also been reported in patient serum, and they have been shown to correlate with disease activity.[39,40]

Three FDA-approved biologics inhibit TNF-α: infliximab, adalimumab, and etanercept. Although all three drugs inhibit TNF-α, they are structurally diverse and have differing pharmacodynamic and pharmacokinetic profiles. For example, infliximab and adalimumab bind to both soluble and membrane-bound TNF, whereas etanercept binds primarily to soluble TNF.[41] Infliximab and adalimumab may also have a greater propensity to cause lymphocyte apoptosis compared to etanercept, as they can lyse cells with membrane-bound TNF through complement activation and/or antibody-dependent, cell-mediated cytotoxicity.[42] In contrast, only etanercept binds lymphotoxin α, a member of the TNF family.[43] In terms of pharmacokinetics, the subcutaneous administration of adalimumab and etanercept leads to smooth and uniform concentration time profiles at steady state, whereas the intravenous dosing of infliximab results in very high peak to trough ratios.[44] Infliximab binds TNF quickly and irreversibly, whereas etanercept sheds about 50 percent of soluble TNF within 10 minutes of binding.[42] The pharmacodynamic and pharmacokinetic differences between TNF inhibitors may result in differing safety and efficacy profiles. For example, infliximab appears to be more efficacious than etanercept in granulomatous diseases such as Crohn disease, sarcoidosis, and Wegener granulomatosis.[42] However, it may also be associated with a higher risk of granulomatous infections.[45] TNF inhibitors are discussed as a class and then certain features of individual TNF inhibitors are highlighted.

Indications. Etanercept is FDA approved for the treatment of psoriasis and infliximab and adalimumab are under review for this indication. All three TNF inhibitors are approved for the treatment of psoriatic arthritis. Additionally, etanercept is FDA approved for rheumatoid arthritis, ankylosing spondylitis, and juvenile rheumatoid arthritis; infliximab is FDA approved for rheumatoid arthritis, Crohn disease, ulcerative colitis, and ankylosing spondylitis; and adalimumab is FDA approved for rheumatoid arthritis. Case reports and small case series suggest potential efficacy of these agents in the management of numerous inflammatory dermatologic conditions that include aphthous stomatitis, Behçet disease, cicatricial pemphigoid, dermatomyositis, eosinophilic fasciitis, hidradenitis suppurativa, multicentric reticulohistiocytosis, necrobiosis lipoidica diabeticorum, pityriasis rubra pilaris, pyoderma gangrenosum, sarcoidosis, scleroderma, Sneddon-Wilkinson syndrome, and SAPHO (synovitis, acne, pustulosis, hyperostosis, and osteitis) syndrome.[46]

Initiating Therapy and Monitoring. TNF inhibitors are immunosuppressive, and therefore, patients should be carefully screened for signs and symptoms of malignancy and infection before initiating therapy and during the course of treatment. Product labeling suggests screening for latent tuberculosis infection with a tuberculin skin test before initiating therapy with infliximab and adalimumab. Published guidelines, however, suggest tuberculosis screening for all three TNF inhibitors.[47] TNF inhibitors should be used with caution in patients with a history of congestive heart failure, and infliximab at doses > 5 mg/kg is contraindicated in patients with moderate to severe congestive heart failure. Infliximab may be associated with liver function test abnormalities, which, in rare cases, has lead to liver failure. Additionally, infliximab and adalimumab have been associated with reactivation of hepatitis B in patients who are chronic carriers, and some of these cases have been fatal. Therefore, one may consider monitoring liver function tests during TNF therapy and screening patients for hepatitis B if the patient is at risk of hepatitis B infection. Small cases series have suggested that TNF inhibitors can be used safely in patients with hepatitis B when lamivudine is given concurrently. However, larger confirmatory studies are necessary.[48]

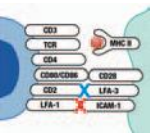
Risks, Precautions, and Complications.

INFECTION. TNF inhibitors are associated with serious infections, including pneumonia, sepsis, tuberculosis, histoplasmosis, and coccidioidomycosis. Product labeling also indicates that for patients who have resided in regions where histoplasmosis and coccidioidomycosis are endemic, the risks and benefits of infliximab and adalimumab therapy should be carefully considered. A recent meta-analysis of rheumatoid arthritis patients treated with infliximab or adalimumab in randomized controlled trials suggested that use of these agents results in one excess serious infection for every 59 patients treated for a period of 3 to 12 months.[49] Use of etanercept with anakinra has been associated with an increased risk of serious infections, and, therefore, it is recommended that anakinra not be used concurrently with any TNF inhibitor.

MALIGNANCY. There is theoretical concern that TNF inhibitors may increase the risk of malignancy. A meta-analysis of patients treated with adalimumab or infliximab in clinical trials of rheumatoid arthritis demonstrated an increased risk of solid organ malignancies compared to placebo.[49] Etanercept was associated with an increased risk of solid organ cancer when given concurrently with cyclophosphamide in a trial for Wegener granulomatosis.[50] Observational cohort studies have indicated a potential increased risk of lymphoid malignancies in rheumatoid arthritis patients treated with infliximab or etanercept.[51,52] It is not certain if the excess risk of lymphoma observed in these observational studies is due to the TNF inhibitor or the severity of the underlying disease (e.g., rheumatoid arthritis), which itself may portend a greater risk of lymphoma. Psoriasis patients may also have an increased risk of lymphoma, independent of biologic therapy, and therefore, addi-

tional studies will be necessary to determine if long-term exposure to biologics impacts lymphoma risk in psoriasis patients.[53] Infliximab has also been associated with aggressive hepatosplenic T-cell lymphomas in post-marketing surveillance of patients with Crohn disease treated with concomitant azathioprine or 6-mercaptopurine. Additionally, aggressive CTCLs have been reported in patients receiving TNF inhibitors.[54]

NEUROLOGIC EVENTS. TNF inhibitors have been associated with rare cases of new onset demyelinating disease and with exacerbation of clinical and radiologic findings in patients with a history of demyelinating disease (e.g., multiple sclerosis).



AUTOIMMUNITY. TNF inhibitors may be associated with the development of anti-nuclear antibodies and anti–double-stranded DNA antibodies compared to placebo, the clinical significance of which is unknown. Rarely, TNF inhibitors have been associated with lupus-like syndromes and vasculitis.

IMMUNIZATIONS. TNF inhibitors may lower the titer response to immunizations; however, the clinical significance of this observation is unknown. Most patients with psoriatic arthritis receiving etanercept were able to mount effective B-cell immune responses to pneumococcal polysaccharide vaccine. Live vaccines should not be used in patients taking TNF inhibitors.

HEMATOLOGIC EVENTS. Rare cases of serious hematologic events have been associated with TNF inhibitors.

PREGNANCY AND LACTATION. TNF inhibitors are pregnancy category B medications with unknown safety during lactation.

INFLIXIMAB Infliximab is a 149-kd monoclonal chimeric antibody that is FDA approved for the treatment of rheumatoid arthritis, psoriatic arthritis, and recalcitrant Crohn disease. It consists of a murine antigen binding region with specificity for human TNF-α fused to a human immunoglobulin G1 (IgG1) constant region. A phase III, double-blind, placebo-controlled trial in patients with psoriasis reported that 80 percent of patients treated with infliximab (5 mg/kg) achieved a Psoriasis Area and Severity Index 75 (PASI-75) at week 10.[55] Although infliximab has demonstrated marked clearing of psoriasis, several recent reports have suggested the potential for infliximab to induce or exacerbate psoriatic disease.[56] The mechanisms underlying this observation remain to be determined. Treatment of psoriatic patients, per clinical trials, has been dosed at 3 mg/kg or 5 mg/kg on weeks 0, 2, 6, and every 8 weeks thereafter.

Through its ability to neutralize both membrane-bound and soluble TNF-α, infliximab is believed to decrease cutaneous inflammation and promote keratinocyte differentiation in psoriatic plaques. In vitro studies also suggest that infliximab may promote disease improvement through an ability to induce apoptosis of lesional keratinocytes.[57]

By nature of its chimeric properties (i.e., possessing both murine and human components), infliximab may be targeted by the host immune system if the murine portion of its structure is identified as foreign.[58] Neutralizing antibodies generated against infliximab have been reported among patients treated for Crohn disease, rheumatoid arthritis, and psoriasis[55,59,60] The generation of neutralizing antibodies is associated with an increased risk of infusion reactions and with decreased efficacy. Strategies to decrease the formation of neutralizing antibodies include use of concomitant immunosuppressive medication (e.g., methotrexate), and regular (as opposed to intermittent) dosing of infliximab. Infliximab is also associated with the development of anti-nuclear antibodies and anti–double-stranded DNA antibodies, the clinical significance of which is unknown. (See Anti-Tumor Necrosis Factor-α for greater detail on indications, initiating and monitoring therapy, risks, precautions, and complications.)

ADALIMUMAB Adalimumab is a fully human, 148-kd monoclonal antibody against TNF-α that has exhibited clinical efficacy in the treatment of rheumatoid arthritis, psoriatic arthritis, and psoriasis. Similar to infliximab, it inhibits TNF-α signaling by binding to both soluble and cell-bound forms of this cytokine. Data from a phase II randomized, double-blind, placebo-controlled trial showed that more than 75 percent of patients with moderate to severe plaque psoriasis achieved a PASI-75 response after 12 weeks of treatment (at a dose of 80 mg qwk for the first two doses, followed by 40 mg qwk) compared to 4 percent of patients receiving placebo.[61] Injection site reactions occur with adalimumab; however, they are generally mild and self-limited. (See Anti-Tumor Necrosis Factor-α for greater detail on indications, initiating and monitoring therapy, risks, precautions, and complications.)

Antibodies Against Cell Surface Receptors

EFALIZUMAB Efalizumab is a recombinant humanized monoclonal IgG1 antibody against the α subunit of the leukocyte function–associated antigen 1 (LFA-1, CD11a). LFA-1 is a member of the β_2 integrin family and is involved in lymphocyte activation, enhanced cytotoxic T-cell function, and the trafficking of lymphocytes to the skin.[62] It recognizes the intercellular adhesion molecule 1 (ICAM-1) expressed on the surface of dermal endothelial cells, an interaction that mediates the firm adhesion, or "arrest," stage of lymphocyte trafficking. This stage is followed by the diapedesis, or migration, of cutaneous lymphocyte associated antigen expressing T cells into the cutaneous microenvironment. ICAM-1 is also expressed by antigen-presenting cells, and its engagement by LFA-1 serves as a co-stimulatory signal for T-cell activation.[63]

In both short- and long-term studies, efalizumab has exhibited efficacy in the treatment of patients with moderate-to-severe psoriasis. In one randomized, double-blind, phase III study, 27 percent of patients receiving efalizumab 1 mg/kg SC qwk) achieved a PASI-75 by week 12 (as opposed to 4 percent of the placebo group); this percentage increased to 44 percent by week 24.[64] Studies to evaluate the biologic activity of efalizumab demonstrated a reduction in LFA-1 cell surface expression by T cells, in addition to histologic improvement of skin lesions.[65,66] A decrease in cutaneous ICAM-1 expression and an increase in circulating lymphocytes has also been noted, suggesting a reduced ability of lymphocytes to traffic into the skin.

Indications. Efalizumab was approved by the FDA in October 2003 for the treatment of patients with moderate to severe plaques psoriasis who are candidates for systemic or phototherapy. It is not effective for the treatment of psoriatic arthritis. Recent case studies suggest the potential efficacy of efalizumab in the management of dermatologic conditions including atopic dermatitis, refractory subacute cutaneous lupus erythematosus, and dermatomyositis.[67–69]

Initiating Therapy and Monitoring. Efalizumab is administered SC as a 0.7 mg/kg initial conditioning dose, followed by weekly administration at a concentration of 1 mg/kg. Initial and periodic assessment of platelet counts and blood counts are recommended, given a risk for thrombocytopenia and hemolytic anemia. One may also consider screening for latent tuberculosis infection before initiating efalizumab; however, this is not currently required, based on FDA labeling.

Efalizumab is a pregnancy category C medication with unknown safety during lactation.

Risks, Precautions, and Complications. Flu-like symptoms have been reported among some patients after the first few doses; however, these symptoms are rare after the third dose, and the incidence can be lowered by starting with a conditioning dose. Exacerbation of psoriasis while on treatment, as well as rebound flares upon abrupt discontinuance of therapy, have also been reported. Patients may develop a mild localized breakthrough of psoriasiform skin lesions during treatment that typically respond well to topical steroids. However, serious flares have included the development of inflammatory, pustular, and erythrodermic psoriasis that occurred in 0.7 percent of patients in clinical trials.[70] Patients experiencing serious flares may require management with hospitalization, cyclosporine, methotrexate, or prednisone. Per packaging information [Raptiva (efalizumab), Genentech, Inc.], thrombocytopenia, hemolytic anemia, and arthritis may arise among some treated patients. In addition, efalizumab is not recommended among patients who are already receiving other immunosuppressive therapies, and acellular, live, and live-attenuated vaccines should not be administered during efalizumab treatment. Efalizumab is immunosuppressive, and therefore may theoretically be associated with a higher risk of infections and malignancies. Long-term studies in large numbers of treated patients are necessary to determine if efalizumab is associated with an increased risk of serious infections and malignancy.

RITUXIMAB Rituximab is a humanized chimeric monoclonal antibody against CD20, a cell surface protein expressed by mature and pre-B cells. CD20 expression is lost during the differentiation of B cells to plasma cells. Aside from playing a crucial role in antibody production, B cells may also serve as antigen-presenting cells and have been shown to provide co-stimulatory signals that promote $CD4^+$ T-cell expansion and effector cell function.[71]

Rituximab is FDA approved for the treatment of patients with moderate to severe rheumatoid arthritis and for the treatment of relapsed or chemorefractory (low-grade or follicular) $CD20^+$ non-Hodgkin B-cell lymphomas and has been shown to transiently reduce the population of $CD20^+$ cells in the circulation.[72] This effect is achieved by its ability to enhance antibody and complement-mediated cytotoxicity, and promote the apoptosis of malignant $CD20^+$ cells.[73] Aside from its role in the treatment of lymphoma and rheumatoid arthritis, rituximab has been increasingly used off-label for the management of other autoimmune diseases. More specifically, recent reports have proposed its efficacy in the treatment of paraneoplastic pemphigus, autoimmune hemolytic anemia, Wegener granulomatosis, hypocomplementemic urticarial vasculitis, systemic lupus erythematosus, cutaneous B-cell lymphoma, and epidermolysis bullosa acquisita.[74]

With regard to dermatologic disease, a case report of a patient with recalcitrant epidermolysis bullosa acquisita responsive to rituximab suggested an apparent increased susceptibility of autoantigen-specific $CD20^+$ B cells to the drug.[75] It has also been used in the treatment of refractory pemphigus.[76] Caution should be taken before initiating therapy with rituximab for off-label use. Recent reports have noted marked progression of Kaposi sarcoma among patients who have received rituximab for autoimmune hemolytic anemia and Castleman disease.[77,78]

Indications. Rituximab is FDA approved for the treatment of $CD20^+$ non-Hodgkin B-cell lymphomas and moderate to severe rheumatoid arthritis.

Initiating Therapy and Monitoring. No specific dosing regimen has been established for the off-label use of this medicine in the dermatologic setting. Rituximab is usually administered at a standard dose of 375 mg/m^2 body surface area at weekly intervals. Premedication with acetaminophen and antihistamines should be considered to decrease the risk for infusion reactions. Monitoring of blood cell counts and serum antibody levels may be pursued every 2 to 3 months while on therapy.

Rituximab is a pregnancy category C medication with unknown safety during lactation.

Risks, Precautions, and Complications. Reported adverse effects associated with rituximab therapy include infusion reactions, hepatitis B re-activation, tumor lysis syndrome, renal toxicity, mucocutaneous reactions, and bowel obstruction/perforation.

FUSION PROTEIN(S)

Alefacept

Alefacept is a bioengineered protein consisting of the human IgG1 antibody Fc region fused to the first extracellular domain of human LFA-3. LFA-3 is a member of the immunoglobulin superfamily and is expressed on the surface of antigen-presenting cells. It normally binds to CD2, which is preferentially expressed on the surface of effector/memory T cells, an interaction that plays an important role in the activation of T cells in response to antigen. Alefacept is believed to prevent the activation of T cells by blocking the interaction between LFA-3 and its CD2 ligand.[79] In addition, it may induce the apoptosis of memory T cells via binding of its IgG1 portion to the CD16 receptor of NK cells.[80]

INDICATIONS Alefacept was the first biologic agent approved for the treatment of psoriasis. It was FDA approved for the treatment of moderate to severe plaque stage psoriasis in January 2003 and has exhibited proven efficacy in the management of adult patients with chronic plaque stage disease. Studies have evaluated the efficacy of both intravenous and intramuscular dosing (7.5 mg intravenously qwk and 15 mg intramuscularly qwk); however, only the intramuscular form is commercially available at this time. A randomized, placebo-controlled phase III trial of adult patients with chronic plaque psoriasis involving at least 10 percent body surface area was performed to address the efficacy and safety of alefacept therapy (15 mg intramuscularly qwk) for 12 weeks.[81] A 75 percent or greater reduction in PASI was achieved by 21 percent of patients and, of those who achieved this degree of response, 71 percent maintained a PASI of at least 50 percent in the 12-week, follow-up period. No opportunistic infections or disease rebound was noted during follow-up.

Reports of the off-label use of alefacept in the treatment of other inflammatory dermatoses such as graft-versus-host disease, lichen planus, and alopecia areata have been described.[82,83] Alefacept has also shown promise in the treatment of psoriatic arthritis either as monotherapy or in combination with methotrexate; however, additional studies are necessary to determine if alefacept is indicated for psoriatic arthritis.[84,85]

INITIATING THERAPY AND MONITORING Alefacept is contraindicated in patients with human immunodeficiency virus infection and should not be used in patients with a $CD4^+$ T lymphocyte count that is below normal. On the basis of published studies and manufacturer recommendations, alefacept treatment is typically initiated as a 15 mg intramuscular dose administered on a weekly basis for 12 weeks, followed by a 12-week period of non-treatment observation. On the basis of a recent study, improved efficacy may be achieved by increasing the initial treatment course to 16 weeks.[86] Phase III clinical trials have shown increased efficacy of alefacept with successive courses of treatment (up to five courses) with no observed compromise in safety or tolerability.[87,88]

Upon initiation of therapy, CD4 and CD8 T-cell counts should be monitored every 2 weeks, and treatment should be withheld if the CD4 count drops below 250 cells/μL, and CD4 counts should then be monitored weekly. If counts remain below this level for more than 4 weeks, then treatment should be discontinued. In general, treatment should not be initiated in patients with low $CD4^+$ T-cell counts or an active infection within 2 weeks of therapy. Consideration of therapy among patients with a history of a prior malignancy should be pursued with caution.

Alefacept is a pregnancy category B medication with unknown safety during lactation.

RISKS, PRECAUTIONS, AND COMPLICATIONS Alefacept is well tolerated with a limited side-effect profile. Pooled data from randomized controlled trials revealed a low incidence of malignancy among treated patients, which was similar to untreated patients. Chills, however, were more common among patients receiving intravenous alefacept relative to placebo.[89] Abnormalities in liver function tests were more frequent in alefacept-treated patients compared to placebo, and serious liver reactions have been reported in the post-marketing arena. Therefore, patients with signs or symptoms of liver injury should be fully evaluated. No correlation between $CD4^+$ T-cell counts and infection has been reported. $CD4^+$ T-cell mediated antibody responses remain intact among treated individuals.[90] Long-term follow-up studies will be necessary to determine if the immunosuppressive properties of alefacept increase the risk of serious infections and malignancies.

Etanercept

Etanercept is a fusion protein consisting of the human TNF type II receptor linked to a human IgG1 Fc region. It blocks the effects of TNF-α by binding to it in the circulation, thus preventing it from associating with its cell surface receptor. In a double-blind, placebo-controlled study, 49 percent of psoriatic patients treated with high-dose etanercept (50 mg twice weekly) for 12 weeks achieved a PASI of at least 75, whereas only 4 percent of patients in the placebo group attained this result.[91] Continued clinical improvement was noted in the subsequent weeks, with 59 percent of high-dose etanercept-treated patients achieving a PASI of 75. It is recommended that therapy for psoriasis be initiated at a dose of 50 mg SC 2×/wk for 12 weeks, then reduced to 50 mg qwk (or 25 mg SC twice weekly). The median time to relapse after discontinuation of therapy after 6 months is estimated at 70 to 91 days.[92] Injection site reactions may occur with etanercept; however, they are generally mild and self limited. (See Anti-Tumor Necrosis Factor-α for greater detail on indications, initiating and monitoring therapy, risks, precautions, and complications.)

Denileukin Diftitox

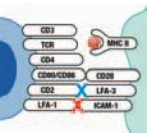
Denileukin diftitox (DAB389-IL2) is a ligand-toxin fusion protein consisting of a fragment of diphtheria toxin, which is involved in translocation and adenosine diphosphate-ribosyltransferase activity, fused to IL-2. DAB389-IL2 is believed to associate with malignant cells expressing the high affinity IL-2 receptor. Upon binding to the receptor, it is internalized within an endosome. It is within this setting that its adenosine diphosphate-ribosyltransferase region is cleaved and translocated into the cytoplasm where it interrupts protein synthesis, eventually leading to apoptosis of the affected cell. Because of its ability to deplete $CD25^+$ T-cells, DAB389-IL2 is believed to contribute toward antitumor immunity through its potential to eliminate regulatory T cells, a specialized population of $CD25^+$ T-cells with immune suppressing properties, in addition to malignant cells that express the CD25 component of the IL-2 receptor.

CD25 represents the α chain of the IL-2 receptor. It serves both as a marker for activated T cells, as well as for a unique population of $CD4^+$ T cells that express the transcription factor, FoxP3, called *regulatory T cells* ($CD4^+CD25^+FoxP3^+$). Naturally occurring regulatory T cells exhibit immunosuppressive properties and have been shown to play an important role in the induction of immune tolerance. Murine melanoma models indicate a role for regulatory T cells in suppressing antitumor immunity.[93] In addition, the in vivo use of anti-CD25 specific antibody was shown to deplete regulatory T-cell populations and enhance tumor regression in the murine system.[94]

In a phase III, double-blind, placebo-controlled study, patients with advanced or refractory CTCL were randomized to receive DAB389-IL2 by infusion at doses of 9 μg/kg/day or 18 μg/kg/day.[97] All patients had failed at least one prior therapy (the median number of prior therapies was five) and were shown to have at least 20 percent CD25 expression among tumor cells in the skin. Treatment was administered for 5 consecutive days and was repeated every 3 weeks for up to eight treatment cycles. Intent to treat analysis revealed a 30 percent clinical response rate among all treated patients, characterized by a ≥ 50 percent reduction in tumor burden. Ten percent of patients achieved a complete clinical response characterized by no evidence of cutaneous disease. The majority of patients exhibited a clinical response within the first three treatment cycles. The durability of response was higher among complete responders with a median of nine months. The median duration of response among partial responders was 4 months. No statistically significant difference in response was noted between the two dosing groups.

INDICATIONS DAB389-IL2 is FDA approved for the treatment of CTCL in which the malignant cell population expresses the CD25 receptor.

INITIATING THERAPY AND MONITORING DAB389-IL2 is administered intravenously over at least 15 minutes. Doses at 9 μg/kg/day and 18 μg/kg/day have been used for the treatment of CTCL.



DAB389-IL2 is a pregnancy category C medication with unknown safety during lactation.

RISKS, PRECAUTIONS, AND COMPLICATIONS Infusion-associated hypersensitivity reactions represent the most common adverse effect associated with DAB389-IL2 treatment. Such reactions have been characterized by fever, hypotension, arthralgias, dyspnea, rash, and chest/back tightness. DAB389-IL2 has also been associated with flu-like symptoms, a reversible transaminitis, vascular leak syndrome, and a morbilliform cutaneous eruption. DAB389-IL2 is contraindicated among patients with a known hypersensitivity to any of its components.

CONCLUSION

In this chapter, we have discussed a number of biologic agents currently available for the management of dermatologic disease. As we further characterize the immunopathogenesis of cutaneous disease, new potential targets for therapy may be identified, thus improving our ability to treat conditions that may otherwise be poorly responsive to conventional therapies. Targeting of the immune system with biologics may result in an increased risk of serious infections and malignancies. Large, prospective, long-term, follow-up studies will be necessary to fully describe the safety of these agents. Additionally, immunobiologics require complex manufacturing processes and are generally very expensive, which may limit their use.

ACKNOWLEDGMENT

The authors would like to thank Dr. Alain H. Rook for his insight and useful discussions in the preparation of this chapter.

CHAPTER 236

Anti-Angiogenic Agents

Kalpana Reddy
Jack Arbiser

In 1971, Judah Folkman published a landmark paper that hypothesized that all tumor growth is dependent on angiogenesis and hypothesized that inhibitors of angiogenesis could be used to treat cancers: The field of angiogenesis research was born.[1]

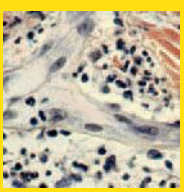
Anti-angiogenic drugs can be classified as either "direct" or "indirect," the former acting directly on untransformed endothelial cells to prevent proliferation, migration, or survival, which normally occurs upon stimulation by pro-angiogenic molecules, and the latter inhibiting tumor-produced oncogene protein products that promote pro-angiogenic state. Angiogenesis inhibitors are a promising new class of drugs because they are effective against slow-growing tumors, while traditional therapies, such as chemotherapy and radiation, work best on rapidly dividing cells. In the future, patients with clinically undetectable cancers may be able to stop the switch to an angiogenic phenotype, and thus prevent disease progression, by using therapies directed, in part, by angiogenesis biomarkers.[2,3] Fig. 236-1 shows the key points of action of some of the anti-angiogenic drugs discussed in this chapter in normal skin, pre-cancerous lesions, and malignancy.

BEVACIZUMAB (AVASTIN)

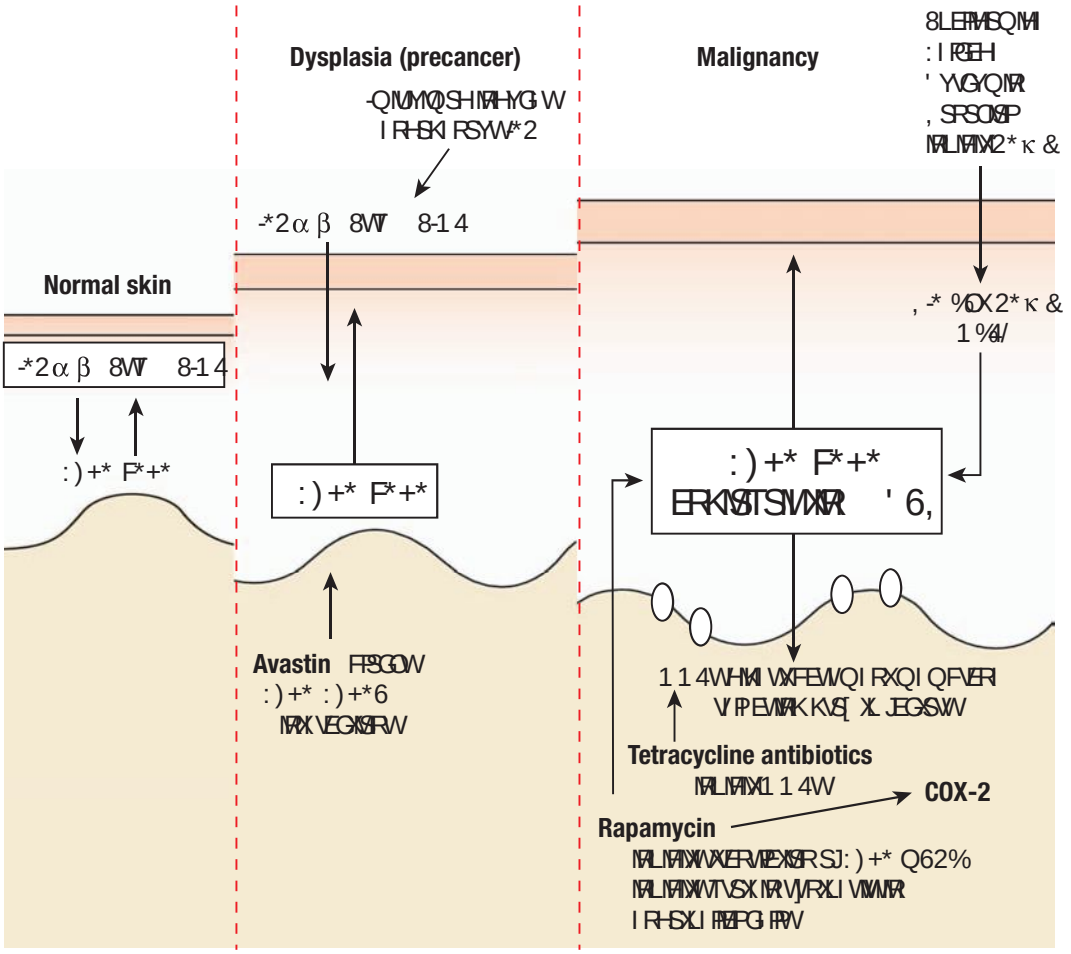
Mechanism of Action

Bevacizumab is a recombinant, humanized, immunoglobulin G1 monoclonal antibody against vascular endothelial growth factor (VEGF). VEGF is a

ANTI-ANGIOGENIC AGENTS AT A GLANCE



- "Direct" anti-angiogenic agents act directly on untransformed endothelial cells to prevent proliferation, migration, and survival.
- "Indirect" anti-angiogenic agents inhibit tumor-produced oncogene proteins that promote a pro-angiogenic state.
- Anti-angiogenic agents are a promising new class of drugs because they are effective against slow-growing tumors.



▲ **FIGURE 236-1** Schematic depiction of the key points of action of some of the anti-angiogenic drugs discussed in this chapter in normal skin, pre-cancerous lesions, and malignancy. bFGF = basic fibroblast growth factor; COX-2 = cyclooxygenase 2; CRH = corticotropin-releasing hormone; HIF = histoplasma inhibitory factor; IFN = interferon; MAPK = mitogen-activated protein kinase; MMP = matrix metalloproteinase; mRNA = messenger RNA; NF-κB = nuclear factor κB; TIMP = tissue inhibitor of metalloproteinases; Tsp-1 = thrombospondin 1; VEGF = vascular endothelial growth factor; VEGFR-2 = vascular endothelial growth factor receptor 2.

growth factor that promotes angiogenesis by supporting endothelial cell replication and survival. This potent pro-angiogenic molecule is upregulated in a majority of human tumors and alters tumor vasculature.

Binding of bevacizumab to VEGF is direct and specific. The antibody also competitively binds VEGF receptor 1 (VEGFR-1) and VEGFR-2, preventing VEGF from binding to its receptors and initiating the signaling cascade. Bevacizumab also reduces and normalizes tumor vascularity.[4]

Indications

Bevacizumab was the first anti-angiogenesis drug approved by the U.S. Food and Drug Administration (FDA) in February 2004 for the first-line treatment of patients with metastatic carcinoma of the colon or rectum, when given in combination with intravenous 5-fluorouracil-based chemotherapy. Bevacizumab is currently being investigated in clinical trials for use in other advanced cancers such as malignant melanoma. No known contraindications to bevacizumab therapy exist.[5]

Complications

- Gastrointestinal perforation
- Wound dehiscence (Incisions should be healed completely before treatment initiation)
- Serious hemorrhagic events
- Arterial thromboembolic events[6]

INTERFERON-α 2B

Interferon-α (IFN-α) made history in 1988 as the first anti-angiogenic therapy used in humans, for the successful treatment of pulmonary hemangiomatosis in a pediatric patient. IFN-α 2b is a product of recombinant molecule and has similar actions to its natural endogenous counterpart, α-IFN, a type I IFN produced naturally by the immune system.

Mechanism of Action

The IFNs act by binding to their receptor, resulting in signal transduction through the Janus kinase-signal transducers and activators of transcription (Jak-STAT) pathway. IFN-α, which is both a direct and indirect anti-angiogenic agent, was first discovered to impair capillary endothelial cell migration. Its properties as an indirect anti-angiogenic agent include its ability to decrease tumor cell production of basic fibroblast growth factor (bFGF), which may explain its success in treating hemangiomas, which overexpress this pro-angiogenic factor.[3]

IFN-α has a well known antiviral activity and antitumor activity, which may be mediated in part by upregulating major histocompatibility complex class I antigen expression, activating natural killer cells, controlling progres-

sion through cell cycle checkpoints, and activating apoptosis.

Pharmacokinetics

IFN-α 2b is given by subcutaneous, intramuscular, intravenous, or intralesional routes. Its half-life is 2 to 3 hours. The drug is likely metabolized by the kidneys. Polyethylene glycol IFN-α 2b has a 10-fold increase in the half life, decreased toxicity, and increased compliance.[7]

Indications

Infections:

- Chronic hepatitis B (may be chemopreventive against hepatocellular carcinoma)
- Chronic hepatitis C
- Acquired immunodeficiency syndrome (AIDS)–associated Kaposi sarcoma
- Condylomata acuminata

Malignancies:

- Malignant melanoma (adjuvant to surgical therapy in patients at high risk of systemic recurrence; must be administered within 56 days postoperatively)
- Hairy cell leukemia
- Follicular lymphoma

Contraindications

- Hypersensitivity to IFN-α or any drug components
- Combination IFN-α and ribavirin therapy in pregnancy or in males whose female partners are pregnant, or in autoimmune hepatitis. Sarcoidosis has been observed in patients who are on combined IFN-α–ribavirin therapy.

Dosing Regimen (Table 236-1)

TABLE 236-1
Interferon-α 2b Dosing

DISEASE	DOSE
Malignant melanoma high-dose regimen	Induction: 20 million IU/m^2 IV infusion, 5 consecutive days/wk for 4 wk Maintenance: 10 million IU/m^2 SC three times/wk for 48 wk
Malignant melanoma adjuvant low-dose regimen (in clinical trials)	Maintenance: 3 million U SC three times/wk for 1 yr
Acquired immunodeficiency syndrome–related Kaposi sarcoma	30 million IU/m^2 SC or IM three times/wk until disease progression or maximal response has been achieved after 16 wk
Condylomata acuminata	1 million IU per lesion (maximum of five lesions per course) three times/wk on alternate days for 3 wk May administer a second course at 12–16 wk
Hemangiomas	3 million U/m^2/day for at least 6 mo[8]

Initiating Therapy

Hemoglobin, complete blood cell count with differential, electrolytes, liver function tests, thyroid-stimulating hormone, chest x-ray, and eye examination should be obtained before initiation of and during therapy. Patients with prior cardiac disease or advanced cancer require an electrocardiogram. Therapy should not be initiated in patients with a history of depression or severe psychiatric disorder due to the risk of psychiatric symptoms and suicide. Patients with thyroid disorder that cannot be corrected with medication should not be treated. The development of paraplegia in hemangioma patients taking IFN has been noted; however, more recently, these patients were found to be severely hypothyroid due to the presence of ectopic thyroxin degrading enzymes produced by the hemangioma. Thus, thyroid monitoring should be mandatory in all patients with large hemangiomas.

Monitoring Therapy

Treatment should be discontinued if neutrophil counts reach less than 0.5×10^9/L or platelet counts reach less than 25×10^9/L. Other symptoms warranting discontinuation include new-onset or worsening eye symptoms, the development of thyroid dysfunction uncorrectable by medication, and the development of severe depression or other psychiatric disorder during therapy.

Risks and Precautions

Pregnancy category C.

Complications

FLU-LIKE SYMPTOMS Symptoms such as headache, fatigue, fever, chills, myalgia, and anorexia are common during therapy.

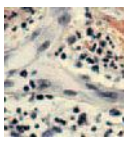
DEPRESSION IFN-α therapy can result in new-onset depression or worsen preexisting depression. Patients should be monitored during therapy for severe depression, and therapy should be discontinued if necessary.[9]

THALIDOMIDE (THALOMID)

Thalidomide was first released in Europe and several other regions in the late 1950s and quickly became a popular sedative, frequently used for the treatment of nausea in pregnancy. Thalidomide was not approved in the United States at the time due to its questionable safety in pregnancy and evidence of peripheral neuropathy. The drug was, however, approved for use in clinical trials in the United States and was given to more than 1000 physicians in the United States for this purpose before it was banned as a sedative after the discovery that the drug caused severe embryopathy, resulting in phocomelia, amelia, or other severe birth defects when taken during pregnancy. The world's tragic experience with thalidomide prompted dramatic changes in drug regulation and approval.

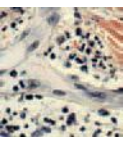
In 1965, Sheskin prescribed thalidomide for psychosis in one of his patients and accidentally discovered that thalidomide effectively treated her erythema nodosum leprosum (ENL). The FDA approved thalidomide in 1998 for the treatment of ENL and currently classifies thalidomide as an orphan drug.

As interest in thalidomide's ability to treat a wide variety of refractory diseases grows, a promising class of drugs named *ImiDs®* or *immunomodulatory thalidomide analogues*, has come under development and testing. One member of this new class of drugs, lenalidomide (CC-5013, REVLIMID®), is being tested in clinical trials for the treatment of multiple myeloma, myelodysplastic syndromes, and chronic lymphocytic leukemia. Phase III clinical studies of lenalidomide for the treatment of metastatic Malignant melanoma did not show a significant effect.[10]



Mechanism of Action

Thalidomide exhibits a wide range of effects in vitro and in vivo. Its mechanisms of action are still under investigation. The drug decreases tumor necrosis factor-α (TNF-α) and IFN-γ levels, as well as having other immunomodulatory effects. Treatment reduces inflammation and pain in ENL patients, as well as neuritis, iritis, and iridocyclitis. Thalidomide also has anti-angiogenic properties and inhibits bFGF-mediated angiogenesis. Its anti-angiogenic properties may be the basis for its antineoplastic activity and may also contribute to its teratogenicity.[11] Other mechanisms by which thalidomide acts include hypnosedative actions, immunomodulation, and anti-inflammatory actions. Effects on the immune system include a reduction in helper T cell–suppressor T-cell ratio, decreased leukocyte chemotaxis and monocyte phagocytosis, decreased production of several cytokines including TNF-α, interleukin 4 (IL-4), IL-5, and IFNs. Human keratinocytes have increased migration and proliferation with thalidomide treatment.



Pharmacokinetics

Thalidomide has low water solubility and slow absorption from the gastrointestinal tract, reaching peak plasma levels 5 hours after administration, and it is only available in an oral form. A delay in absorption of up to 2 hours may occur if given in conjunction with high-fat foods.

Thalidomide's half-life is 10 hours. The total body clearance is estimated to be 10 L/hour. Thalidomide's main route of elimination remains unknown. Thalidomide is metabolized by nonenzymatic hydrolysis, and therefore is unlikely to affect levels of cytochrome P_{450}-metabolized drugs such as oral contraceptives. Acetylcholine, prostaglandins, histamine, and serotonin are antagonized by thalidomide in vitro. Alcohol, barbiturates, chlorpromazine, and reserpine have enhanced activity in the presence of thalidomide.

Indications

Thalidomide was FDA approved for the acute treatment of the cutaneous manifestations of moderate to severe ENL and has also been approved for maintenance therapy for prevention and suppression of the cutaneous manifestations of ENL recurrence. All other uses are considered experimental.

TABLE 236-2
Thalidomide Dosing for Selected Dermatologic Diseases

Erythema nodosum leprosum	Initial dose: 100–300 mg/day Maintenance dose: 50–100 mg/day
Severe cutaneous erythema nodosum leprosum reaction	Initial dose: 400 mg/day
Chronic graft-versus-host disease	Initial dose: 100 mg qid Maintenance dose: 200–400 mg qid Pediatric dose: 3.0–9.5 mg/kg bid to qid
Cutaneous lupus erythematosus	Initial dose: 400 mg/day Maintenance dose: 25–50 mg/day
Recurrent aphthous stomatitis	100 mg/day
Behçet syndrome	Initial dose: 400 mg/day Maintenance dose: 200 mg/day[12]

A common off-label use of thalidomide is for the treatment of severe aphthous stomatitis, especially in AIDS patients. Although the precise inciting cause of aphthous stomatitis remains unknown, the stomatitic lesion is highly angiogenic and expresses high levels of VEGF and VEGFR-2 and TNF-α. The coexistence of TNF-α and angiogenesis in the same lesion is reminiscent of psoriasis as well as ENL. Thalidomide has activity against a variety of inflammatory angiogenic conditions, perhaps through a common mechanism.

Contraindications

- Pregnancy
- Hypersensitivity to the drug or its components

Dosing Regimen

Guidelines for dosing include initiation at 100 to 300 mg/day with water at bedtime because thalidomide may induce drowsiness. Therapy should be continued until improvement is noted, at which point the physician can begin tapering the dose by 50 mg every 2 to 4 weeks. In the case of maintenance therapy, an attempt at tapering should occur every 3 to 6 months (Table 236-2).

Initiating Therapy

Thalidomide therapy should be reserved for patients with debilitating, serious diseases that have proved to be refractory to other therapies. The manufacturer of thalidomide has developed a restricted distribution program called *System for Thalidomide Education and Prescribing Safety* (S.T.E.P.S®). The program requires both prescribers and dispensing pharmacists to be registered, and it is mandatory for patients to be informed about the program and adhere to its requirements. Female patients of childbearing potential (defined by the program as sexually mature women who have not undergone a hysterectomy or who have not been post-menopausal for at least 24 consecutive months) must have a negative pregnancy test within 24 hours of treatment initiation. Patients must use reliable contraception (two effective methods unless using the abstinence method) for a period of at least 1 month before initiating therapy and must continue this practice during and for 1 month after therapy is completed. Male patients are required to use latex condoms, even in patients who have had a vasectomy.

Monitoring Therapy

S.T.E.P.S® requires patient monitoring during therapy. Strict guidelines for pregnancy testing are outlined for females of childbearing potential to prevent potential fetal damage, and guidelines are given for male patients as well. If, during the course of therapy, a patient becomes pregnant, the drug should be immediately stopped and the exposure reported to the FDA and the manufacturer (Celgene). Patients should then see an obstetrician/gynecologist with experience in reproductive toxicity.

Risks and Precautions

- Hypersensitivity
- Bradycardia
- Stevens-Johnson syndrome and toxic epidermal necrolysis
- Seizures
- Pregnancy category X

Complications

TERATOGENICITY Thalidomide's embryopathy is well-documented. Thalidomide is pregnancy category X, and patients selected for therapy must follow strict contraceptive measures as directed by the program. Thalidomide-induced defects in limb formation may be due to bFGF inhibition, as bFGF has been shown to induce embryologic limb formation.

PERIPHERAL NEUROPATHY Thalidomide is neurotoxic and may result in a sensory, symmetrical distal polyneuropathy, which may later evolve to include motor symptoms as well. Neurotoxicity can be permanent. Incidence of peripheral neuropathy in patients receiving thalidomide ranges from 0.5 percent to 25.0 percent. Patients with pre-existing peripheral neuropathy should not begin treatment. Baseline nerve conduction studies should be obtained before treatment initiation, with monitoring at 6-month intervals during treatment. A 40 percent decrease in nerve conduction necessitates treatment discontinuation.

OTHER SIDE EFFECTS Other side effects include drowsiness, orthostatic hypotension, neutropenia, rash, fever, and human immunodeficiency virus viral load increase.[12,13]

RAPAMYCIN (SIROLIMUS) (See Chap. 234)

Mechanism of Action

Isolated from the bacterium *Streptomyces hygroscopicus*, rapamycin is a macrocyclic lactone antibiotic with immunosuppressant, antifungal, and antineoplastic properties. Rapamycin acts by inhibiting the interaction of the mammalian target of rapamycin (mTOR) with its substrates, thereby disrupting the signaling pathway. mTOR is a serine-threonine protein kinase activated by several growth factors after receptor-binding. mTOR activates downstream targets that affect cell cycle control and angiogenesis in neoplastic cells.[14] Rapamycin has been shown to significantly inhibit vascular endothelial cell stimulation by VEGF and inhibits bFGF-mediated angiogenesis.[15] Of the drugs used in the solid organ transplant setting (rapamycin, cyclosporine, tacrolimus), rapamycin has the greatest anti-angiogenic activity, and it may be useful for the prevention of squamous cell carcinoma and lymphoma in the transplant population, especially because chronic use of cyclosporine and tacrolimus are risk factors for cancer development.

Indications

Rapamycin is an FDA-approved drug used as an immunosuppressant to prevent renal transplant rejection, as well as an agent in drug-eluting cardiac stents to prevent restenosis after coronary artery angioplasty. It is currently in clinical trials as an anti-angiogenic agent for cancer therapy and is being studied for the treatment of psoriasis, tuberous sclerosis, and lymphangioleiomyomatosis.

Complications

SYSTEMIC COMPLICATIONS Complications that may occur include headache, thrombocytopenia, arthralgia, interstitial pneumonitis, and hypercholesterolemia.[14]

CUTANEOUS EFFECTS Cutaneous side effects of therapy include angioedema, leukocytoclastic vasculitis, xerosis, and aphthous ulceration, which all resolve with discontinuation of therapy.[16]

BECAPLERMIN

Chronic wounds have become increasingly prevalent in recent years with the rise in diabetes and the increasingly aging population. Treatment of these wounds is particularly challenging because the normal wound-healing process has been disrupted in these patients.

Mechanism of Action

Becaplermin [recombinant human platelet-derived growth factor (PDGF) BB] is the first FDA-approved angiogenesis-stimulating therapy. Endogenous PDGF is chemotactic for several cell types necessary for wound healing. PDGF is also a mitogen for fibroblasts, which produce the extracellular matrix components glycosaminoglycans and fibronectin. Thus, PDGF is an important factor in the formation of granulation tissue.

Indications

Becaplermin gel is indicated for the treatment of lower extremity diabetic neuropathic ulcers. The ulcers must be adequately oxygenated and must reach to at least the subcutaneous tissue.[17] Becaplermin gel is contraindicated in patients with known cancer in the treatment area.

Dosing Regimen

Becaplermin gel should be applied topically once daily. The dose should be recalculated every 1 to 2 weeks to ensure accurate dosing as the wound changes size. Becaplermin gel should be used along with proper ulcer care.

Monitoring Therapy

If there is less than a 30 percent decrease in size after 10 weeks or if the wound has not completely healed after 20 weeks of treatment, the treatment plan should be re-evaluated.

Risks and Precautions

Because becaplermin gel is non-sterile, it should not be applied to wounds closed by primary intention. Becaplermin gel is pregnancy category C.

Complications

- Hypersensitivity reaction
- Ulcer-related complications (incidence was similar in becaplermin vs. placebo groups)[18]

BORTEZOMIB

Mechanism of Action

Bortezomib is the first proteasome inhibitor to gain FDA approval. This novel class of drugs acts by impairing the ability of the proteasome to degrade a variety of ubiquitinated proteins. Proteasome inhibitors may promote a pro-apoptotic state by preventing the degradation of tumor-suppressor proteins, such as p53, and other proteins, such as inhibitors of nuclear factor κB (NF-κB), which negatively regulates NF-κB. NF-κB upregulates the transcription of genes involved in neoplastic progression, including VEGF.[19] Bortezomib is being studied for use in both hematologic and solid malignancies in combination with chemotherapy and radiation regimens because it has been shown to decrease chemoresistance, which is correlated with NF-κB activity. Bortezomib also acts directly to inhibit VEGF, IL-6, insulin-like growth factor 1, angiopoietin 1, and angiopoietin 2 transcription.[20]

Indications

Recurrent or refractory multiple myeloma.

Contraindications

Hypersensitivity to bortezomib, boron, or mannitol.[21]

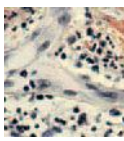


TABLE 236-3
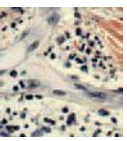
Anti-Angiogenic Properties of Selected Experimental Drugs

DRUG	ANTI-ANGIOGENIC EFFECTS
Curcumin (diferuloylmethane)	Decreases pro-angiogenic factors, decreases endothelial cell proliferation, decreases neovascularization[26,27]
Calcium dobesilate	Binds and antagonizes basic fibroblast growth factor[28]
Honokiol	Inhibits VEGFR-2 autophosphorylation, blocks activation of Rac (necessary for endothelial cell migration and proliferation) in response to vascular endothelial growth factor[29]
Interleukin 12	Decreases basic fibroblast growth factor-mediated angiogenesis, stimulates natural killer cells to exhibit cytotoxicity against endothelial cells, acts through interferon-γ to induce interferon-inducible protein 10, an anti-angiogenic chemokine, and downregulates matrix metalloproteinase synthesis[8,30]
BAY 43-9006 (Sorafenib)	Receptor tyrosine kinase inhibitor which inhibits multiple tyrosine kinases, including Raf, VEGFR-2, VEGFR-3, platelet-derived growth factor receptor-β, FLT-3, and c-kit kinases[31]

VEGFR = vascular endothelial growth factor receptor.



IMIQUIMOD (See Chap. 221)

Mechanism of Action

Imiquimod is both the first immune response modifier and the first topical anti-angiogenic agent for dermatologic use. Imiquimod acts by inducing the activation of Toll-like receptor 7 in immune cells. Toll-like receptor 7 activation enhances the natural immune response by increasing endogenous IFN and IL production, including IFN-α, IFN-β, IFN-γ, IL-10, IL-12, and IL-18. These cytokines also function as endogenous angiogenesis inhibitors, and the upregulation of these cytokines, as well as other endogenous angiogenesis inhibitors, such as IFN-inducible protein 10, tissue inhibitor of metalloproteinases, and thrombospondin 1, is the basis for imiquimod's anti-angiogenic activity. Imiquimod also downregulates pro-angiogenic factors such as bFGF and matrix metalloproteinase 9. In vivo, imiquimod has been shown to inhibit angiogenesis in human bowenoid papulosis, hemangioendothelioma, cutaneous melanoma, and murine lung sarcoma cells. Imiquimod is FDA approved to treat actinic keratosis, superficial basal cell carcinoma, and external genital warts. It is being studied as an experimental therapy for the treatment of angiogenic dermatologic conditions such as squamous cell carcinoma, lentigo maligna, hemangiomas, Kaposi sarcoma, and pyogenic granuloma (Table 236-3).[22–25]

CHAPTER 237

Drug Interactions

Stephen E. Wolverton

DRUG INTERACTION PRINCIPLES

The topic of drug interactions is strikingly complex and rapidly evolving. Even "experts" in this area of pharmacology must rely on print and electronic resources pertaining to drug interactions on a regular basis. With these facts in mind, this chapter focuses on a wide variety of principles, with selected drug interactions utilized to illustrate these principles, as opposed to providing extensive lists of potential drug interactions. Furthermore, there is an attempt to provide a stratification of risk, putting the greatest emphasis on the drug interactions with the greatest risk to individual patients. The electronic version has much more detail and references. The print edition emphasizes useful summary tables.

Definitions

The most basic definition of a drug interaction is when two drugs are present simultaneously in a patient, and one drug alters the other's serum/tissue levels or mechanism of action.

Print and Electronic Resources

Through learning key principles that assist in attaining the broadest possible understanding of the multitudes of potential interactions, a clinician may best be able to interpret and react to new clinician situations involving potential drug interactions. One should always attempt to make things "make sense" using the general principles that follow. It is always acceptable to (1) call a drug information pharmacist, (2) call or e-mail an expert in drug interactions, or (3) look up possible interactions in various print and electronic resources. Selected resources for drug interactions are listed in Table 237-1.

P-Glycoprotein

PHARMACOKINETIC AND PHARMACODYNAMIC DRUG INTERACTIONS[1]

Definitions

All drug interactions can be divided into either pharmacokinetic or pharmacodynamic interactions, whether they are an adverse drug interaction or an interaction without loss of drug efficacy or the onset of new toxicity. Pharmacokinetics deals with "what the body does to the drug," whereas pharmacodynamics deals with "what the drug does to the body."

Various Sub-Types of Pharmacokinetic Drug Interactions

Pharmacokinetic drug interactions are much more common than pharmacodynamic drug interactions. This category of interactions results from alterations in a drug's serum and/or tissue levels. The ADME model (see Sub-Types of Metabolic Drug Interactions) of studying pharmacokinetics pertains to this category of interactions. The steps from entry of the drug into the body until excretion of the drug and/or its metabolites include (1) *a*bsorption, (2) *d*istribution, (3) *m*etabolism, and (4) *e*xcretion. The importance of each of these steps is detailed elsewhere.[2,3] Examples of drug interactions involving each of these steps are included in Table 237-2.

Various Sub-Types of Pharmacodynamic Interactions

Pharmacodynamic drug interactions are much less common than pharmacokinetic drug interactions. This category of interactions deals with alterations in the mechanism of either the desired pharmacologic effect or mechanism for an adverse effect. The drug levels are not of central importance in this category of interactions. The two primary sub-types of interactions include (1) agonist—similar "polarity" of the pharmacologic effects for the two interacting drugs, and (2) antagonist—opposite "polarity" of the pharmacologic effects for the two interacting drugs. Both agonist and antagonist interactions can produce either a positive (improved therapeutic response or safety) or negative (toxicity) biologic response. Selected examples to illustrate this innately confusing terminology are listed in Table 237-3.

Sub-Types of Metabolic Drug Interactions

Isoforms of Cytochrome P_{450} of Greatest Importance to Drug Interactions

The importance of cytochrome P_{450} enzyme 3A4 (CYP 3A4) and CYP 2D6 lies in the fact that these isoforms metabolize about 50 percent and 20 percent to 25 percent of all drugs, respectively. Due to some overlap of drug substrates that are metabolized by both CYP isoforms, roughly two-thirds of all drugs are metabolized by at least one of these two pathways. Other CYP isoforms of greatest potential importance to drug interactions include CYP 2C9, CYP 2C19, CYP 1A2, and CYP 2E1.

DRUG SUBSTRATES, INHIBITORS, AND INDUCERS[1,3]

Drug Substrates

A substrate is basically a drug in the process of being metabolized to a more water soluble form (metabolite) to enable excretion. A substrate may "travel" down one or more than one metabolic pathway, including possibly more than one CYP isoform. The metabolic pathway may be either a CYP isoform, a non-CYP pathway (phase II), or both. Furthermore, a substrate may also be an inhibitor or inducer of the drug's metabolic pathway. An example would be cyclosporine, which is both a substrate and inhibitor of CYP 3A4.

Substrates of greatest interest for three of the most important CYP isoforms are listed in Table 237-4. References listed in Table 237-1 can be consulted for more comprehensive lists of CYP isoforms and pertinent drug substrates.

Substrates That Are Narrow Therapeutic Index Drugs

A given drug's "therapeutic index" is merely the ratio of the drug dose producing the desired therapeutic response versus the drug dose producing toxicity.

TABLE 237-2
Pharmacokinetic Steps Pertaining to Drug Metabolism and Interactions

Pharmacokinetic Step	Primary Interactions	Examples
Absorption	Loss of efficacy	Divalent cations and tetracyclines or fluoroquinolones ↑ Gastric pH (antacids) and itraconazole or ketoconazole
Distribution	Toxicity	Nonsteroidal anti-inflammatory drugs and methotrexate Sulfonamides and methotrexate
Metabolism	Loss of efficacy and toxicity	Examples in Tables 237-5 through 237-10
Excretion	Toxicity	Sulfonamides and methotrexate Digoxin and cyclosporine

TABLE 237-3
Pharmacodynamic Categories of Drug Interactions

Category	Examples	Comments
Agonist interaction—same polarity of mechanism		
Positive pharmacologic effect	Prednisone and azathioprine	"Steroid-sparing" effects
Negative pharmacologic effect	Hydroxychloroquine and chloroquine	↑ Risk of retinopathy
Antagonist interaction—opposite polarity of mechanism		
Positive pharmacologic effect	Methotrexate and folic acid	↓ Methotrexate adverse effects
Negative pharmacologic effect	β Blockers[a] and epinephrine[b]	Unopposed α-adrenergic effects, ↑↑ blood pressure

[a]Non-cardioselective β blockers.
[b]Epinephrine at very high doses if very high volumes of lidocaine with epinephrine are used during a procedure (very rare).

TABLE 237-4
Some Important Substrates for Several Important Cytochrome P_{450} (CYP) Isoforms

CYP 3A4 Substrates	CYP 2D6 Substrates	CYP 2C9 Substrates
Antibacterial agents	Analgesics	Antibacterial agents
• Erythromycin	• Codeine	• Sulfonamides
• Rifampin	• Meperidine	Anticoagulants
Anticoagulants	• Morphine	• S-Warfarin enantiomer
• R-warfarin enantiomer	Antidysrhythmics	Anticonvulsants
Antidysrhythmics	• Encainide	• Phenytoin
• Amiodarone	• Flecainide	• Valproic acid
• Digoxin	• Mexiletine	Nonsteroidal anti-inflammatory drugs
• Lidocaine	• Propafenone	• Diclofenac
Calcium channel blockers—all	β Blockers	• Ibuprofen
H_1 antihistamines[a]	• Metoprolol	• Piroxicam
• Fexofenadine	• Propranolol	Statins
• Loratadine	Selective serotonin reuptake inhibitor antidepressants	• Fluvastatin
Statins	• Fluoxetine	• Rosuvastatin
• Atorvastatin	• Paroxetine	
• Lovastatin	Tricyclic antidepressants	
• Simvastatin	• Amitriptyline	
Hormonal contraceptives	• Clomipramine	
Immunosuppressive agents	• Desipramine	
• Cyclosporine	• Doxepin	
• Tacrolimus		

[a]Terfenadine and astemizole are 3A4 substrates. They have been taken off the market in the United States. Note: This table is intended to give important examples and is far from comprehensive; for more complete information, consult database of Dr. David Flockhart at Indiana University Department of Medicine (see Table 237-1). Adapted from Shapiro LE, Shear NH: Drug interactions, in ' SQTVLI RMMI (I VQEXSRKG(VMK8LI VET] 2nd ed, edited by Wolverton SE. London, Elsevier, 2007, p 949.

A drug with a "narrow" therapeutic index would represent drugs for which the ratio is relatively close to the number 1 regardless of which is the numerator and denominator. Several examples of relatively narrow therapeutic index drugs are listed in Table 237-5.

Enzyme Inhibitors

An enzyme "inhibitor" is a drug that slows/decreases the rate of metabolism of another drug substrate. Visualizing this process in a traffic analogy, the inhibitor blocks the flow of traffic (drug metabolism) on a shared road (CYP isoform or a phase II metabolic pathway).

Two of the strongest inhibitors of CYP 3A4 are erythromycin (macrolide antibiotics) and ketoconazole (azole antifungals). In each of these drug groups, there are alternatives that have little or no inhibitory effect on the CYP isoform involved in the potential drug interaction of interest. Examples of variations of enzyme inhibition within a drug group are listed for inhibitors of CYP 3A4, CYP 2D6, and CYP 2C9 in Table 237-6.

Enzyme Inducers

An enzyme "inducer" is a drug that speeds up the metabolism of a drug substrate. The inducer facilitates traffic on the "highway" (metabolic pathway) for drug metabolism.

Most CYP enzyme inducers affect more than one CYP isoform. Some of the strongest enzyme inducers include rifampin and the aromatic anticonvulsants phenytoin, phenobarbital, and carbamazepine. Griseofulvin is also an enzyme inducer, albeit a relatively weak one. Some clinical scenarios pertinent to dermatology of enzyme induction of significant importance are listed in Table 237-7.

Genetic Polymorphisms[4]

The term *polymorphism*, as it pertains to drug metabolism, merely represents a mutation in a phase I or phase II enzyme that results in clinically important differences of enzyme activity compared with normal. Conceptually, "variability" results in a unimodal distribution (a single bell-shaped curve), whereas a genetic polymorphism creates a bimodal distribution (at least two bell-shaped curves) when putting enzyme activity on a graph. Clinically significant polymorphisms involving drug metabolizing enzymes most notably include both phase I enzymes (CYP 2D6 and CYP 2C9) and phase II enzymes (*N*-acetyltransferase-2 and thiopurine methyltransferase). These polymorphisms can result in (1) drug interactions, (2) altered metabolism of a drug used as monotherapy, or (3) cutaneous or systemic drug interactions. Table 237-8 summarizes examples of the clinical outcomes in these three categories from the above four enzyme polymorphisms.

CLINICAL SCENARIOS

Varying Risk of Individual Drug Interactions

Not all drug interactions are "adverse" drug interactions; these pharmacokinetic and pharmacodynamic interactions do not result in an adequate change in drug levels or mechanisms of action to have clinical importance. Furthermore, only a small percentage of drug interactions have a life-threatening potential. At the conclusion of the chapter, 12 of the most potentially serious drug interactions pertinent to dermatology are highlighted. In between these two extremes is where the majority of drug interactions exist. In these

TABLE 237-5
Selected Narrow Therapeutic Index Drugs

Category	Drug Name	Cytochrome P_{450} Isoform	Most Important Acute Toxicities
Anticoagulants	Warfarin	2C9, 3A4, 1A2	Hemorrhage (thrombosis if effect inhibited)
Antidepressants	Doxepin[a]	2D6	Excessive sedation, tachyarrhythmias
Bronchodilators	Theophylline	1A2	Central nervous system toxicity
Immunosuppressive agents	Cyclosporine	3A4	Renal toxicity, hypertension, hyperlipidemia
	Methotrexate	None[b]	Pancytopenia, liver toxicity
Inotropic agents	Digoxin	3A4	Cardiac tachyarrhythmias, atrioventricular block

[a]Overall, doxepin is the safest drug on this list; however, in the presence of strong cytochrome P_{450} (CYP) 2D6 inhibitors, central nervous system and cardiac toxicity are important issues.
[b]As opposed to CYP inhibition with other drugs above, the greatest risk of methotrexate toxicity is with concomitant use of drugs such as trimethoprim (dihydrofolate reductase inhibitor) and sulfamethoxazole (dihydropteroate synthetase inhibitor), which also inhibit enzymes important to folate metabolism.

TABLE 237-6
Variability within a Drug Class—Enzyme Inhibitors

Drug Category	Cytochrome P_{450}	Strong Inhibitor	Weaker Inhibitor	No Effect
Macrolides/azalides	3A4	Erythromycin	Clarithromycin	Azithromycin
	1A2	Erythromycin		Clarithromycin, azithromycin
Azole antifungals	3A4	Ketoconazole	Itraconazole	Fluconazole
	2C9	Fluconazole		Ketoconazole, Itraconazole
SSRI antidepressants	2D6	Fluoxetine, paroxetine	—	Other SSRIs

SSRI = selective serotonin reuptake inhibitor.
Adapted from Shapiro LE, Shear NH: Drug interactions, in ' SQTVLI RVMI (I VQEXSPSHKG(VWK8LI VET] 2nd ed, edited by Wolverton SE. London, Elsevier, 2007, p 949.

TABLE 237-7
Clinical Scenarios in Which Enzyme Inducers Lead to Loss of Efficacy

Substrate	Enzyme Inducer	Cytochrome P_{450} Isoform	Clinical Result
Warfarin	Rifampin[a]	3A4	Thrombosis if significant loss of anticoagulant
Hormonal contraceptives	Rifampin[a]	3A4	Possible unintended pregnancy
	Griseofulvin	3A4	Possible unintended pregnancy
Cyclosporine, tacrolimus	Rifampin[a]	3A4	Loss of transplanted organ (graft)

[a]Given that enzyme induction generally takes 1 week or more to reach clinical significance, a 7- to 10-day course of rifampin (as commonly prescribed for community-acquired methicillin-resistant 7XETL] PSGGGVW EVVYVWay fall short of the time period for maximal risk; however, appropriate caution (ideally avoid co-prescribing) is required in these clinical settings.
Note: The drugs listed in this table are drugs that are commonly prescribed by dermatologists; the aromatic anticonvulsants—carbamazepine, phenobarbital, and phenytoin and several other drugs are also important enzyme inducers.

clinical settings, the clinician has a great deal of flexibility concerning therapeutic choices. From these three categories, one can derive one additional traffic analogy:

1. Adverse drug interactions with life-threatening potential (*red* light)—do not proceed (e.g., fluconazole and warfarin; must choose an alternative such as itraconazole or terbinafine).
2. Adverse drug interactions of clinical importance, but not life threatening (*yellow* light)—proceed with caution [see examples in Therapeutic Options with "Proceed with Caution" (Yellow Light) Clinical Scenario].
3. Other drug interactions of no clinical risk due to minor effect of "interaction" on drug levels or mechanisms of action (*green* light)—can proceed with drug combination and can reassure the patient.

Therapeutic Options with "Proceed with Caution" (Yellow Light) Clinical Scenario

Typically, there is substantial latitude concerning yellow light clinical scenarios. The clinician may choose to avoid the drug combination altogether if there are suitable drug alternatives or if the disease being treated presents minimal risk to the patient. Alternatively, the clinician may choose one or several of the following options: (1) lower the drug dose—azathioprine and allopurinol, for which 75 percent reduction of azathioprine dose is recommended, (2) monitor closely from a clinical standpoint—doxepin and an selective serotonin reuptake inhibitor (SSRI) antidepressant such as paroxetine or fluoxetine, following the level of sedation closely, and/or (3) appropriate laboratory testing—can order morning doxepin serum levels with CYP 2D6 inhibitors such as paroxetine or fluoxetine. Concerning the doxepin/SSRI interaction described above, the clinician may choose to use an SSRI antidepressant alternative that does not inhibit the CYP 2D6 pathway (e.g., citalopram, escitalopram, or sertraline). From a proactive standpoint, baseline genetic testing of either the CYP 2D6 and CYP 2C19 polymorphisms are readily available. This genetic testing may determine in advance the rate of metabolism by the specific CYP isoform. Possibilities include the following (listed in descending order from the most rapid to the slowest rate of drug metabolism:

1. Ultrarapid metabolizer—uncommon, may involve gene "duplication"
2. Extensive metabolizer—most common subset, homozygous for the "wild type" (full metabolic activity) gene
3. Intermediate metabolizer—relatively frequent, heterozygous for the "wild type" gene

TABLE 237-8
Clinical Relevance of Drug Metabolism Enzyme Polymorphisms

Polymorphism	Specific Drug	Drug Interaction	Monotherapy Result	Drug Reaction
Phase I enzymes				
CYP 2D6	Doxepin	Paroxetine, fluoxetine (↑ severity in IM, PM)	Toxicity (sedation) PM Loss of efficacy EM, URM	None
CYP 2C9	Warfarin	Fluconazole	Toxicity (hemorrhage) PM Loss of efficacy (thrombosis) URM	None
Phase II enzymes				
2acetyltransferase-2	Isoniazid	None	None	Drug-induced lupus erythematosus
Thiopurine methyltransferase	Azathioprine	Allopurinol (↑ severity in IM, PM)	Toxicity (pancytopenia) IM, PM Loss of efficacy EM	None

CYP = cytochrome P_{450}; EM = extensive metabolizers; IM = intermediate metabolizers; PM = poor metabolizers; URM = ultrarapid metabolizers.

TABLE 237-9
Options with "Proceed with Caution" Type of Drug Interactions

Clinical Option[a]	Examples
Clinical scenario—want to prescribe doxepin for pruritus in patient on either paroxetine or fluoxetine	
Clinical monitoring	Watch closely for sedation
Laboratory monitoring	Order a morning doxepin level
Lower drug dose	Dose doxepin very conservatively
Alternative drugs to prescribe	Have primary physicians switch to an alternative selective serotonin reuptake inhibitor antidepressant or a non-selective antidepressant SV Could prescribe hydroxyzine, cetirizine, etc.
Baseline genetic testing	Could order baseline cytochrome P_{450} 2D6 genotype testing to see if patient a poor metabolizer
Clinical scenario—want to prescribe erythromycin for acne to a patient on simvastatin	
Clinical monitoring	Could monitor for muscle pain or weakness (by itself, never an option)
Laboratory monitoring	Monitor muscle enzymes (creatine phosphokinase, aldolase)
Lower drug dose	Lower dose of either erythromycin or simvastatin
Alternative drugs to prescribe	Azithromycin a suitable macrolide SV Prescribe an alternative antibiotic group; also request primary physician to consider fluvastatin, rosuvastatin, pravastatin
Clinical scenario—want to prescribe itraconazole for extensive tinea corporis to a patient on warfarin[b]	
Clinical monitoring	Could monitor for bruising/hemorrhage elsewhere (by itself, never an option)
Laboratory monitoring	Follow international normalized ratio (INR) values very closely
Lower drug dose	Lower dose of either the itraconazole or warfarin (through primary physician)
Alternative drugs to prescribe	Terbinafine and topical antifungals are primary alternatives

[a]In each clinical scenario, more than one option may be undertaken simultaneously.
[b]With patients on warfarin, for whom clinicians wish to give fluconazole, these "proceed with caution" options are not pertinent; fluconazole and warfarin is a "red light" scenario in which co-prescribing these drugs must be totally avoided.

4. Poor metabolizer—also uncommon, homozygous for the gene mutation (low/absent metabolic activity)

Some additional examples of the "proceed with caution" scenarios illustrating these therapeutic options are listed in Table 237-9.

Lessons to Be Learned from Drugs Taken Off the Market

There are some important lessons to be learned from drugs interactions that produced life-threatening risk which led to several drugs taken off the market. Two issues are worth highlighting concerning the drug interactions that led to drug removal. In both cases a known CYP enzyme inhibitor (CYP 3A4 inhibitors) was commonly co-prescribed with a CYP 3A4 drug substrate with a narrow therapeutic index. Secondly, in each case, the U.S. Food and Drug Administration published warnings in the form of "Dear Doctor" letters (subsequently known as *Dear Health Care Professional* letters) that, in retrospect, did not bring about an adequate change of clinician-prescribing habits to warrant drug continuation. Several of the potentially life-threatening drug interactions leading to drug withdrawal include the following:

1. H_1 antihistamines terfenadine and astemizole—torsades de pointes (strong CYP 3A4 inhibitors erythromycin or ketoconazole commonly co-prescribed with these drugs)
2. Hepatic 3-methylglutaryl coenzyme A reductase inhibitor cerivastatin (a "statin")—rhabdomyolysis (a strong CYP 3A4 inhibitor gemfibrozil commonly co-prescribed with this drug)

CONCLUSION—A DOZEN DRUG INTERACTIONS OF IMPORTANCE TO PRACTICING DERMATOLOGISTS

There are numerous potential drug interactions for the clinician to consider. When trying to pick a starting point to understand adverse drug interactions, it is logical to start with the most potentially serious drug interactions. With this principle in mind, I have compiled a list of a dozen drug interactions potentially serious, and thus, of great importance to practicing dermatologists and other clinicians utilizing these drugs (Table 237-10).

TABLE 237-10
A Dozen Critical Drug Interactions

	Specific Toxicity	Category		Cytochrome P_{450}	Substrates	Precipitant Drugs
1.	Torsades de pointes	PK	Tox	3A4	Terfenadine, astemizole, cisapride	Erythromycin, ketoconazole, itraconazole
2.	Pancytopenia	PK	Tox	—	Methotrexate	Trimethoprim/sulfamethoxazole
3.	Agranulocytosis	PK	Tox	—	Azathioprine	Allopurinol
4.	Hemorrhage	PK	Tox	2C9	Warfarin	Fluconazole
5.	Thrombosis/embolism	PK	LOE	3A4	Warfarin	Rifampin
6.	Sedation	PK	Tox	2D6	Doxepin	Fluoxetine, paroxetine
7.	Sedation	PD	Tox	—	Doxepin	H_1 antihistamines—sedating
8.	Renal failure/rhabdomyolysis	PK	Tox	3A4	Cerivastatin	Gemfibrozil (and other 3A4 inhibitors)
9.	Renal toxicity	PK	Tox	3A4	Cyclosporine	Erythromycin, ketoconazole, itraconazole
10.	Renal toxicity	PD	Tox	—	Cyclosporine	Gentamicin (and other potentially renal toxic drugs)
11.	Liver toxicity	PD	Tox	—	Methotrexate	Acitretin (previously etretinate)
12.	Loss of transplanted organ	PK	LOE	3A4	Cyclosporine	Rifampin, rifabutin

LOE = loss of efficacy; PD = pharmacodynamic; PK = pharmacokinetic; Tox = toxicity.
Note: These critical drug interactions are listed roughly in descending order of risk.

With proper awareness of drugs for which potential interactions need to be considered and regular usage of drug interaction databases, clinicians can reduce the incidence of adverse drug interactions. Patient education is likewise essential to minimizing this risk. In the vast majority of cases, a less-risk therapeutic alternative is typically available if the print/electronic resources indicate a potential drug interaction. Finally, when in doubt, do not prescribe the drug or drugs in question until a definitive answer on the safety of co-prescribing the medications in question can be answered.

PHYSICAL TREATMENTS

CHAPTER 238

Therapeutic Photomedicine: Phototherapy

Jean Krutmann
Akimichi Morita

Over the past few years, the development of irradiation devices with new emission spectra has led to an expanded role for phototherapy in the treatment of skin disease.[1] This development is best illustrated by the increasing frequency with which 311-nm ultraviolet B (UVB) phototherapy is used for the treatment of psoriasis.[2] In fact, in Europe 311-nm UVB (narrowband UVB) is currently used more often than psoralen and ultraviolet A light (PUVA) therapy for psoriasis and several other cutaneous diseases. Another example is ultraviolet AI (UVAI, 340 to 400 nm).[3] UVAI was first used to treat patients with atopic dermatitis, but it has since been found to be efficacious in several other skin diseases, notably localized scleroderma, where other therapeutic options are limited. These two examples demonstrate that the introduction of new spectra into dermatologic phototherapy has not only broadened and improved phototherapy as it relates to established indications but, in addition, has fostered the development of new indications for phototherapy such as connective tissue diseases. Fig. 238-1 shows the UV spectra used in the treatments discussed in this chapter.

PHOTOTHERAPY OF PSORIASIS (See Chap. 18)

One important option in the long-term management of moderate to severe psoriasis is UVB phototherapy. Within recent years, the availability of new fluorescent bulbs with an emission spectrum that closely conforms to the peak of the action spectrum for clearing psoriasis[4] has significantly improved the efficacy of UVB phototherapy for psoriasis.

311-nm Ultraviolet B: The Phototherapy of Choice for Psoriasis

Parrish and Jaenicke demonstrated that wavelengths shorter than 295 nm displayed no anti-psoriatic effect, even if used at erythemogenic doses, whereas wavelengths between 300 and 313 nm caused the greatest remission of skin lesions.[4] These seminal observations provided the rationale for the development of more selective UVB phototherapy irradiation devices. These units have a spectrum that is still broadband UVB but is enhanced in the range of 300 to 320 nm compared to conventional fluorescent bulbs. As predicted, these light sources proved to be superior to conventional UVB phototherapy for clearing of psoriasis. A major breakthrough was achieved by the development of the Philips TL-01 fluorescent lamp, emitting a narrow UV band at 311/312 nm and thereby matching closely the assumed therapeutic optimum for psoriasis.[2] A large number of clinical trials comparing broadband versus 311-nm UVB phototherapy for psoriasis have been conducted mainly in Europe and, more recently, in the United States. Based on these studies, which increasingly follow randomized controlled designs, it is now generally accepted that 311-nm UVB therapy is superior to broadband UVB therapy for psoriasis.[5,6] Patients treated with a 311-nm spectrum show faster clearance of skin lesions, fewer episodes of excessive erythema, and a longer period of remission (Fig. 238-2). This difference in efficacy has been attributed to the fact that 311-nm UVB is capable of more efficiently depleting skin-infiltrating T cells from the epidermis and dermis of psoriatic plaques as compared with broadband UVB.[7] Also, comparative studies of 311-nm UVB phototherapy and systemic PUVA demonstrate that these two modalities are equally effective and that 311-nm UVB is superior to bath PUVA therapy.[6,8–11] This is of particular interest because 311-nm UVB therapy, in comparison with PUVA, does not require

THERAPEUTIC PHOTOMEDICINE: PHOTOTHERAPY AT A GLANCE

- Phototherapy has greatly benefited from the introduction of selective spectra for specific skin diseases.
- The best phototherapy for psoriasis is 311-nm (narrowband) ultraviolet B (UVB).
- A combination of UVB phototherapy with topical or systemic drugs increases therapeutic efficacy and reduces side effects.
- Severe, acute, and moderate chronic atopic dermatitis are treated with different phototherapeutic modalities.
- Localized scleroderma can be effectively treated with UVAI phototherapy.
- Phototherapy works largely through the induction of apoptosis and immunosuppressive effects.

a systemic photosensitizer, is cheaper, can be used in pregnancy and childhood, and does not require post-treatment eye protection. It has also been suggested that 311-nm UVB may be less carcinogenic than PUVA, although follow-up studies to determine the true carcinogenic risk of 311-nm UVB therapy are currently lacking.[12,13] For these reasons, 311-nm UVB therapy currently represents the phototherapeutic modality of choice for the treatment of psoriasis in Europe and is being used increasingly in the United States, where introduction was delayed by reimbursement issues.

Practical Aspects

For 311-nm UVB therapy, no specific irradiation devices are needed because the Philips TL-01 fluorescent lamps can be fitted into conventional PUVA cabinets. Certain guidelines should be followed regardless of whether 311-nm UVB or conventional broadband UVB from fluorescent bulbs (such as Westinghouse FS, Philips TL12, Sylvania UV21) or medium-pressure mercury arc lamps with or without metal halides are used.[14]

Ideally, before phototherapy, the patient's minimal erythema dose (MED) is determined to establish the optimal dosage schedule. For determination of the MED and subsequent phototherapy, either the same irradiation device or devices with an identical emission spectrum must be used. For 311-nm therapy, which is suitable for all patients regardless of skin type and MED,[15] the initial dose should equal 0.7 MED. Patients are treated three to five times per week. If the initial dose is tolerated, a 20 percent incremental increase of the previous dose is used at each visit.[16] When a previous treatment results in erythema, no treatment is given the next scheduled visit or the dose is decreased, depending on whether the erythema is asymptomatic or painful. It should be noted that 311-nm UVB is also very efficient when used at sub-erythemogenic doses. As well, a regimen with 5 percent or 10 percent dose increments may be as therapeutic as with a 20 percent increment.[15,17]

For broadband UVB therapy, one MED is given on the first treatment and is increased by 50 percent, 40 percent, 30 percent, and so on, in subsequent treatments. Because UV radiation is a complete carcinogen, the genitalia and chronically light-exposed areas (e.g., the face, neck, dorsa of hands), if unaffected, should be shielded or protected (with sunscreen) before irradiation.

For limited psoriasis, 308-nm excimer laser therapy or non-laser 308-nm monochromatic excimer light may represent an option (see Chap. 240).[18,19] The 308-nm excimer laser appears to be highly effective even in otherwise therapy-resistant psoriasis. 308-nm monochromatic excimer light has been found to be particularly suited for the treatment of palmo-plantar pustular psoriasis.[20,21] Both 308-nm light sources can clear patch psoriasis in a similar manner to standard phototherapy with the advantage of selectively treating lesional skin, thus sparing the surrounding normal skin from unnecessary exposure.[19,22,23]

The goal of phototherapy is complete clearance of all psoriatic skin lesions. Psoriasis, however, is a chronic disease and the remission induced by UVB phototherapy is often transient. In a randomized, prospective, multicenter trial, post-clearing phototherapy was found to significantly increase the disease-free interval, indicating that patients may profit from maintenance phototherapy.[24] On the other hand, maintenance therapy results in a greater cumulative UVB dose, increasing the risk of skin cancer and photoaging. It is therefore preferable, if possi-

▲ **FIGURE 238-2** Patient with severe generalized psoriasis before (**A**) and after (**B**) 15 treatments with 311-nm ultraviolet B phototherapy. (Used with permission from J. Ferguson, MD, Dundee, Scotland.)

ble, to maintain remissions with other anti-psoriatic modalities. To minimize potential carcinogenic risks from chronic UVB phototherapy, a rotational therapeutic approach has been suggested.[25]

Combination Therapy

Phototherapy of psoriasis is frequently used in combination with topical or systemic agents to achieve higher clearance rates, longer disease-free intervals, and a lower carcinogenic risk.[25] Topical agents include anthralin, vitamin D analogues, retinoids, glucocorticoids, emollients, saltwater baths, and tar. Among these, anthralin and tar are mainly of historical interest and are not discussed.

Anti-psoriatic vitamin D analogues include calcipotriol, tacalcitol, and calcitriol, which have antiproliferative as well as anti-inflammatory effects (see Chap. 18).[26] Local side effects are limited to moderate skin irritation.[27] To avoid systemic side effects from percutaneous absorption, in particular hypercalcemia with consequent nephrocalcinosis, the treated body surface should not exceed 30 percent.[28] Main indications are psoriatic plaques of limited extent and lesions on the scalp, face, palms, and soles and in the intertriginous areas. The combination of either broadband UVB or 311-nm UVB therapy with calcipotriol increases the therapeutic efficacy of phototherapy alone.[29] This observation is of particular interest because UVB therapy reduces the irritation caused by calcipotriol. Vitamin D analogues should be applied after (not before) phototherapy, because UVA radiation leads to degradation of vitamin D_3.

Another promising combination phototherapy of psoriasis is narrowband UVB irradiation and topical tazarotene gel. Tazarotene is a topical acetylenic retinoid that is efficacious in plaque-type psoriasis. The addition of tazarotene to broadband or narrowband UVB phototherapy was found to promote more effective, faster clearing of psoriasis when compared with either type of phototherapy alone.[30,31] Pre-treatment with tazarotene gel three times per week for 2 weeks before phototherapy increases UV penetration into skin, and thus, UVB and PUVA therapy can be initiated at lower doses than usual.[32]

Several studies have asked whether the efficacy of UVB phototherapy for psoriasis may be enhanced through combination with topical glucocorticoids. Data from these studies are conflicting, and the beneficial effects seem to be limited.[33] Topical glucocorticoids are useful, however, for treating psoriatic lesions in skin areas not reached by UV irradiation during phototherapy (e.g., scalp, groin, perianal area, umbilicus), or for the treatment of lesions recalcitrant to standard phototherapy. They may also be used in the early, highly inflammatory state of psoriasis to achieve a quick improvement.

Topical application of emollients alters the optical properties of psoriatic lesions,[34] improving UV transmission and increasing efficacy.[35] In contrast, thick applications of petrolatum and water-in-oil–type creams and salicylic acid act as sunscreens.

Balneophototherapy comprises the combination of saltwater baths with UVB phototherapy, intended to mimic the successful Dead Sea regimen for the treatment of patients with recurrent severe psoriasis.[36–38] Approaches to balneophototherapy using synthetically generated Dead Sea salt or sodium chloride solutions (usually between 5 percent to 15 percent) for saltwater baths are hampered by logistics (the requirement for bathtubs) and environmental concerns related to disposal of large amounts of salt.

Systemic agents in combination with phototherapy used to treat psoriasis include retinoids, glucocorticoids, cyclosporin A, and methotrexate. Retinoids are the most widely used agents for systemic treatment in combination with phototherapy. In contrast, the systemic use of glucocorticoids in combination with photo(chemo)therapy is limited to special indications, such as generalized pustular psoriasis. Also, combination regimens of UVB therapy with methotrexate or cyclosporin A are not advisable, because both substances increase the possibility of UV-induced skin tumors.

From a theoretical point of view, the advantage of combining retinoids and UVB irradiation is twofold: (1) retinoids exert anti-psoriatic effects and might act synergistically with UVB phototherapy; and (2) they have anticarcinogenic effects and thereby could lower the skin cancer risk resulting from long-term UVB therapy. Because of potentially severe side effects, the use of systemic retinoids should be limited to pustular or erythrodermic variants of psoriasis. Combination regimens with broadband UVB or selective UVB phototherapy with etretinate improved psoriatic patients more quickly than phototherapy alone, and reduced the number of treatments and cumulative UV doses.[39] Similar results were obtained when acitretin, the major metabolite of etretinate, was used in combination with broadband UVB or 311-nm UVB therapy.[40]

PHOTOTHERAPY OF ATOPIC DERMATITIS

In the past few years, UVA/UVB,[41] 311-nm UVB,[42] and UVAI phototherapy[43] were developed to treat atopic dermatitis. As a consequence, dermatologists now have multiple phototherapeutic modalities from which to tailor their treatment to the particular needs of a particular patient. Treatment decisions can also be based on the effectiveness of a given form of phototherapy for a specific stage of atopic dermatitis (i.e., acute and severe vs. chronic and moderate disease activity).

Ultraviolet AI Phototherapy for Acute, Severe Atopic Dermatitis

UVAI phototherapy is a highly effective monotherapy for a limited period of time (10 to 15 exposures). It is most effective for the treatment of patients with a severe, acute exacerbation of atopic dermatitis (Fig. 238-3).[44] Because potential long-term risks of UVAI phototherapy are not known, patients should not be treated over extended periods of time, for example, for maintenance therapy. For the same reason, its use is not recommended for patients younger than 18 years of age. The therapeutic effectiveness of UVAI irradiation in the management of patients with atopic dermatitis was first evaluated in an open study in patients with acute, severe exacerbations of atopic dermatitis.[44] They were exposed to 130 J/cm^2 UVAI daily for 15 consecutive days. Its therapeutic effectiveness was assessed by means of a clinical scoring system as well as by monitoring serum levels of eosinophil cationic protein, a laboratory parameter that can be measured objectively and correlates well with disease activity in atopic dermatitis. In that study, UVAI phototherapy was found to promptly induce clinical improvement and reduce elevated serum eosinophil cationic protein levels. Patients treated with UVAI were compared with subjects who had been treated with UVA/UVB phototherapy. Significant differences in favor of UVAI therapy were observed.[44] These results were recently corroborated and extended in a randomized, controlled multicenter trial in which UVAI therapy, compared with topical glucocorticoid treatment, was

▲ **FIGURE 238-3** Patient with severe, acute exacerbation of atopic dermatitis before (**A**) and after (**B**) high-dose ultraviolet AI therapy (15×130 J/cm^2 ultraviolet AI).

significantly better in reducing the clinical score at day 10.[45]

The therapeutic effectiveness of UVAI therapy is dose-dependent. Low-dose UVAI (30 J/cm^2) is less effective than UVA/UVB therapy,[46] whereas high-dose UVAI therapy (130 J/cm^2) is superior to UVA/UVB phototherapy.[44,45] In addition, a medium-UVAI dosage schedule (50 J/cm^2) was superior to a low-dose UVAI regimen (10 J/cm^2), whereas no significant difference was detected in a bilateral comparison study between a medium- and a high-dose regimen.[47]

High-dose UVAI phototherapy may not be used on patients with UVA-sensitive atopic dermatitis or photodermatoses, and it is therefore necessary to exclude these diseases before initiation of therapy. This can easily be accomplished by photoprovocation testing. Except for eczema herpeticum, no acute side effects have been observed in any of the patients treated with high-dose UVAI therapy. No other side effects have been observed, although carcinogenic risk is a theoretical concern.[48,49] Until more is known about high-dose UVAI therapy, its use should be limited to periods of acute exacerbation of atopic dermatitis and, in general, one treatment cycle should not exceed 10 to 15 daily exposures and should not be repeated more than once per year.[43]

Phototherapy of Chronic, Moderate Atopic Dermatitis

Broadband UVB,[50] combined UVA/UVB,[41,51] broadband UVA,[52] low-dose UVAI,[46] and, in particular, 311-nm UVB phototherapy[52] are effective treatments in mild and moderate atopic dermatitis. They are not particularly effective in patients with acute, severe exacerbations of their disease. In contrast to UVAI therapy, these forms of UV therapy are usually not used as monotherapy. Rather, they are used in combination regimens with topical glucocorticoids to reduce the need for glucocorticoid application. All of these therapies are considered to be relatively safe, even if used over extended periods of time, and they should be used to induce long-term improvement. Patients do best if severe disease is initially controlled by more potent modalities. For example, 311-nm UVB phototherapy has proved to be an ideal modality for maintenance therapy after high-dose UVAI has been used in the initial phase of management of an acute, severe exacerbation of atopic dermatitis.[43] If high-dose UVAI therapy is not available, severe atopic dermatitis should be controlled before the start of phototherapy by aggressive topical glucocorticoid therapy or systemic immunosuppressive modalities such as glucocorticoids or cyclosporin A.

Studies directly comparing all the different forms of UV therapy for chronic, moderate atopic dermatitis have not been performed, but recent trials indicate that either UVA/UVB combination therapy or narrowband 311-nm UVB therapy[42,52–54] is superior to conventional broadband UVB, broadband UVA, or low-dose UVAI therapy. Also, narrowband UVB appears to be equivalent to PUVA for this indication.[6,53] The actual choice made for a particular patient also depends on what irradiation devices are available. Jekler and Larkö, in a paired comparison study, observed significant differences in favor of UVA/UVB therapy over broadband UVB therapy.[46] In this trial, patients were allowed to continue the use of topical glucocorticoids and were irradiated three times per week for a maximum of 8 weeks in a UVB MED-dependent manner.

The therapeutic effectiveness of 311-nm UVB therapy for chronic atopic dermatitis of moderate severity was first shown in an open trial conducted by George et al.[42] and was confirmed in a randomized controlled study.[52] As discussed in the section 311-nm Ultraviolet B: The Phototherapy of Choice for Psoriasis, 311-nm UVB therapy may be associated with a reduced risk of skin cancer compared with broadband UVB or with PUVA therapy.[12] The demonstration of 311-nm UVB therapy's effectiveness for treating childhood atopic eczema[55] is therefore of particular interest.

If neither a UVA/UVB nor a 311-nm UVB irradiation device is available, broadband low-dose (0.5 MED) UVB therapy has been shown in placebo-controlled studies to be effective.[50]

PHOTOTHERAPY OF OTHER DISORDERS

In addition to psoriasis and atopic dermatitis, UV therapy is increasingly used for skin diseases that previously had mainly been treated with PUVA [e.g., polymorphous light eruption (PMLE), urticaria pigmentosa, vitiligo, cutaneous T-cell lymphoma (CTCL)] or for which no phototherapeutic approach had been available (e.g., scleroderma and lupus erythematosus).

Phototherapy of Polymorphous Light Eruption and Other Photodermatoses (See Chap. 90)

Patients with PMLE respond abnormally to UV radiation (in particular UVA radiation), resulting in an increased and sustained expression of pro-inflammatory molecules (cytokines, adhesion molecules) and subsequent development of skin lesions. In the majority of PMLE

▲ **FIGURE 238-4** Patient with morphea before (**A**) and after (**B**) high-dose ultraviolet AI therapy.

patients, exposure to early season sunlight induces tolerance, a process that is termed *hardening*. Artificial induction of hardening or artificial photoprotection constitutes the major principle underlying phototherapy of PMLE.[56] The precise molecular mechanisms responsible for hardening are not yet known, but it is generally believed that phototherapy-induced photoprotection is based on the induction of epidermal thickening, pigmentation, and as-yet-to-be-defined immunologic effects. To maintain phototherapy-induced photoprotection, patients must expose themselves frequently to small does of sunlight, because strict avoidance of sunlight exposure will result in a quick loss of the therapeutically induced hardening effect. The use of phototherapy for PMLE is restricted to severe cases that fail to respond to more simple measures such as light avoidance, photoprotective clothing, and use of broad spectrum sunscreens. For these patients, broadband UVB and PUVA therapy have previously been found to be effective, with PUVA giving better results than UVB therapy.[56] Recent studies, however, indicate that 311-nm UVB therapy represents an effective alternative to PUVA. In a recent study, 25 PMLE patients were randomly assigned to either PUVA treatment or 311-nm UVB therapy.[57] When patients were monitored for 4 months following treatment, there was no difference between PUVA and 311-nm UVB therapy with respect to severity of disease and restriction of outdoor activities. For the reasons given in 311-nm Ultraviolet B: The Phototherapy of Choice for Psoriasis, 311-nm UVB therapy may therefore be considered the treatment of choice for PMLE. The efficacy of 311-nm UVB therapy for photodermatoses other than PMLE has not yet been assessed in controlled studies, but observations from a pilot study indicate that patients with actinic prurigo (in particular), hydroa vacciniforme, and erythropoietic porphyria, but not with solar urticaria, may also benefit from 311-nm UVB therapy.[58] In severe, otherwise therapy-resistant forms of solar urticaria, UVA "rush hardening" therapy may represent an option.[59] This novel approach includes multiple daily UVA irradiations at 1-hour intervals and provides significant protection within 3 days.

Phototherapy of Morphea (Localized Scleroderma) (See Chap. 62)

Morphea has a self-limited course, but skin lesions can cause significant morbidity and discomfort, particularly if they extend over joints and cause flexion contractures or if they lead to muscle atrophy and disfigurement.[60] Numerous modalities, including penicillin, penicillamine, antimalarial drugs, cyclosporin A, interferon-γ, and topical or systemic glucocorticoids, have been used, but their efficacy is poor. It was therefore of considerable interest to learn that UVAI phototherapy was of benefited for patients with morphea.[61,62]

In an open study, 10 patients with histologically proven morphea were exposed 30 times to 130 J/cm^2 UVAI radiation.[62] In all patients, high-dose UVAI therapy significantly reduced thickness and increased elasticity of sclerotic plaques as assessed by 20-MHz sonography (Fig. 238-4). Complete clearance was observed in 4 of 10 patients. These changes were not a result of spontaneous remissions, because they were present only in UVAI-irradiated, but not in unirradiated control plaques in the same patients. Similar therapeutic benefit could also be achieved by using a low-dose UVAI regimen.[61] Direct comparison of low-dose versus high-dose UVAI therapy revealed that high-dose UVAI therapy was superior, indicating that the therapeutic efficacy is dose-dependent.[3] Also, medium-dose UVAI seems to be superior to low-dose UVAI or 311-nm UVB phototherapy.[63] Termination of phototherapy was not associated over a 3-month period with loss of the beneficial effects achieved by high-dose UVAI irradiation in 9 of 10 patients, indicating that maintenance therapy may not be required. The precise mechanism by which UVAI therapy acts in morphea is unknown but most likely involves upregulation of collagenase I expression, which was induced about 20-fold in sclerotic skin lesions after successful UVAI phototherapy.[62,64]

In addition to localized scleroderma, UVAI phototherapy has also been reported to be effective in patients with systemic sclerosis and chronic sclerodermic graft-versus-host disease.[65,66]

Phototherapy of Urticaria Pigmentosa

Several studies have demonstrated that PUVA therapy is effective in reducing pruritus and urtication associated with urticaria pigmentosa.[67] In the majority of patients, however, cessation of PUVA therapy leads to recurrence of urticaria pigmentosa after 5 to 8 months. Recent studies suggest that beneficial effects may also be achieved in these patients by UVAI phototherapy.[68,69] In an open study in four adult patients, high-dose UVAI therapy reduced pruritus and urtication from stroking (Darier sign) after three exposures, whereas hyperpigmented skin lesions faded more slowly.[68]

Increased histamine in 24-hour urine was reduced to normal levels. In two patients with migraine headaches and diarrhea, relief from these systemic symptoms and reduction of serum serotonin to normal levels was observed after 10 exposures. No relapse has occurred in any of these four patients more than 2 years after cessation of high-dose UVAI therapy.[68]

Phototherapy of Miscellaneous Disorders

Several reports indicate that 311-nm UVB is a useful and well-tolerated therapy for vitiligo (see Chap. 72) that results in repigmentation in many patients, including Fitzpatrick's skin types IV and V, as well as children.[70-75] Therapeutic responses are achieved with twice weekly irradiations, an initial dose of 0.25 J/cm^2 independent of skin type, and dose increments of 20 percent each treatment. It should be noted, however, that similar to PUVA or khellin (a non-psoralen furocoumarin) plus UVA (KUVA) therapy, certain anatomic sites (hands and digits, feet and toes) did not respond. A right-left comparison study of PUVA versus narrow-band UVB showed no difference in therapeutic efficacy.[73] It is currently unclear whether additional benefit can be achieved by combining 311-nm UVB with topical calcipotriol or tacalcitol.[76,77]

It has been suggested that daily low-dose UVAI irradiation is beneficial to patients with cutaneous lupus erythematosus (see Chap. 156). In an open study, 10 patients with systemic lupus erythematosus were treated with low-dose UVAI irradiation (6 J/cm^2 daily) for various time periods (15 days to 8 months).[78] A decrease in clinical indices of disease activity, most pronounced after 8 months of phototherapy, was observed in all patients. The UVAI irradiation decreased fatigue, arthritis, photosensitivity, skin rashes, and often depression, headaches, and sleeplessness. In addition, anti-Sjögren syndrome A or anti-nuclear antibodies decreased or even disappeared in most patients. These promising results have been confirmed in an 18-week two-phase study using 6 J/cm^2.[79] No side effects were noted, although UVAI irradiation, at least at higher doses, may theoretically exert detrimental effects on the majority of systemic lupus erythematosus patients.

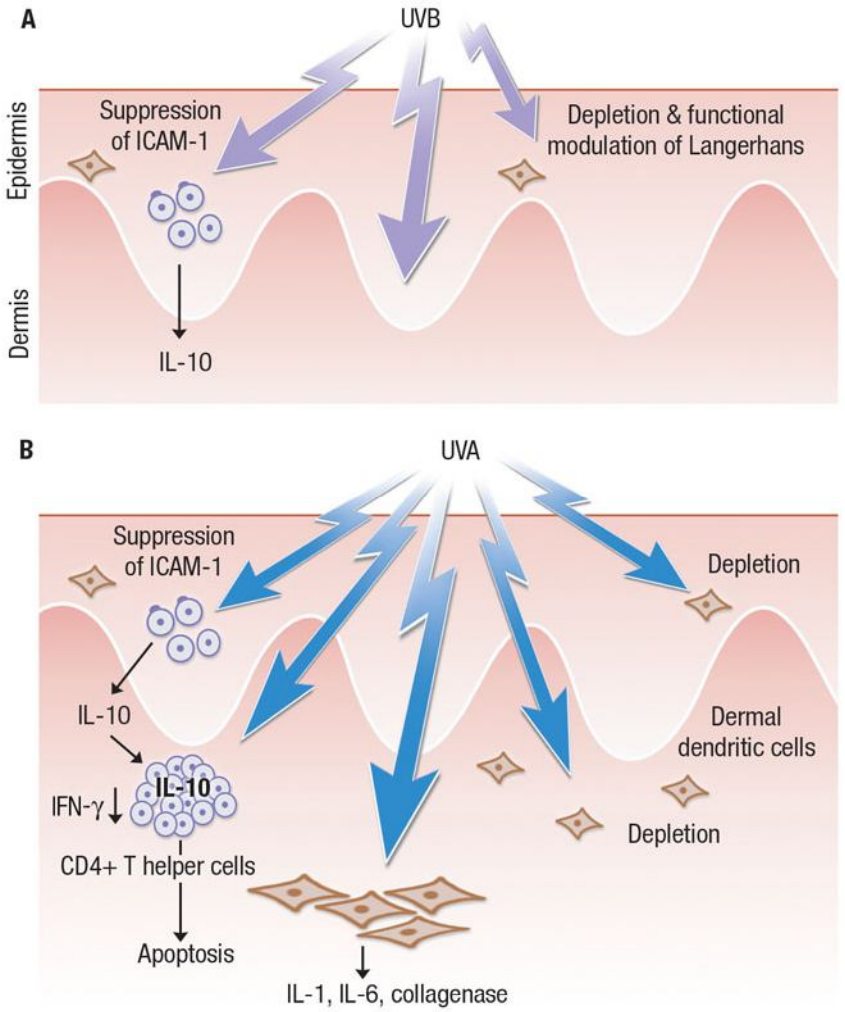
UVAI phototherapy was recently used to treat patients with CTCL (see Chap. 146). In an open pilot study, three of three patients with early stage mycosis fungoides (CTCL stages IA and IB) were treated effectively with a high as well as medium dose UVAI regimen.[80] In a second uncontrolled trial, 11 of 13 patients with widespread plaque-type, nodular and erythrodermic mycosis fungoides (CTCL stages IB, IIB, and III) showed complete clinical and histologic responses upon treatment with a high-dose UVAI regimen.[81] These observations are of particular interest because UVAI phototherapy offers significant advantages over PUVA therapy. Unwanted side effects resulting from the systemic administration of methoxsalen, such as nausea, long-lasting skin photosensitivity, and requirement for eye protection, are completely avoided. There is now also evidence that 311-nm UVB phototherapy can be used to treat early (IA, IB, IIA) stages of mycosis fungoides.[82–84]

Local UVAI phototherapy appears to be an interesting option in the management of patients with chronic vesicular (dyshidrotic) hand eczema.[16] In an open pilot study, palms and backs of hands of 12 patients with an acute exacerbation of their disease were exposed to 15 UVAI irradiations with a dose of 40 J/cm^2 per day over a period of 3 weeks. After 1 week, all but one patient reported a marked relief of itch. After the third week, significant clinical improvement was noted in 10 of 12 patients.[85]

It has recently been shown that wavelengths within the visible range can effectively treat patients with atopic hand and foot eczema (see Chap. 14).[86] This development was prompted by the observation that UVAI phototherapy-induced apoptosis in house dust-mite specific T-cells, which had been cloned from lesional skin of patients with atopic eczema, is mediated through the generation of singlet oxygen. This reactive oxygen species, however, can not only be generated by UV wavelengths, but in particular in the near visible range (Soret band, 400 to 410 nm). A UV-free partial body irradiation device with an emission maximum between 400 and 450 nm has therefore been developed and found to induce prompt and long-lasting improvement in patients with atopic hand and foot eczema.[86] Visible radiation does not increase the risk for skin cancer, and UV-free phototherapy may therefore be well suited for the treatment of children and young adults.

MECHANISM OF ACTION

Through the induction of DNA photoproducts, UVB radiation transiently inhibits cell proliferation. As a result, it was thought that the therapeutic effectiveness of UVB phototherapy in psoriasis is mainly due to its antiproliferative effects. Since the introduction of UVB radiation into dermatologic therapy, however, the number of skin diseases showing a favorable response to phototherapy has grown substantially. The vast majority, including psoriasis, are largely immunologic in nature. Studies on the role of UV radiation-induced immunosuppression in photocarcinogenesis and on the effects of UV radiation on the function of epidermal Langerhans cells have provided increasing evidence that UVB, as well as UVA (and in particular UVAI) radiation, exert profound effects on the skin immune system (see Chap. 88).[106] As a consequence, UVB and UVA phototherapy are currently regarded as modalities whose mechanism of action depends upon immunomodulatory effects that are not specific for a single type of light source. The in vivo relevance of these immunomodulatory effects is dependent on the physical properties of the UV radiation used. On a per-photon basis, wavelengths within the UVB spectrum possess greater energy than UVA wavelengths, but because of their shorter wavelength, they have a more superficial depth of penetration within the skin. As a result, UVB phototherapy primarily affects the function of epidermal keratinocytes and Langerhans cells, whereas UVAI radiation additionally affects dermal fibroblasts, dermal dendritic cells, endothelial cells, T lymphocytes within the dermis, mast cells, and granulocytes[107] (Fig. 238-5). Photoimmunologic effects induced by UVB and UVAI radiation fall into three major categories: (1) effects on soluble mediators; (2) modulation of the expression of cell surface–associated molecules; and (3) the induction of apoptosis in pathogenetically relevant cells. The apoptotic effect is currently thought to be of key importance for phototherapy. Both UVB and UVA (particularly UVAI) radiation are highly efficient in inducing apoptosis in human cells. T cells, compared with monocytes or keratinocytes, have an increased susceptibility to UV radiation-induced apoptosis; this mechanism is, therefore, of particular importance for phototherapy of T cell–mediated skin diseases such as atopic dermatitis, psoriasis, and CTCL.



▲ **FIGURE 238-5** Scheme of immunomodulatory effects induced by ultraviolet B (UVB) (**A**) or UVA phototherapy (**B**). ICAM-1 = intercellular adhesion molecule 1; IFN-γ = interferon-γ; IL = interleukin.

It has been proposed that the greater therapeutic efficacy of 311-nm UVB, as compared with broadband UVB, is due to deeper skin penetration and more efficient induction of apoptosis in dermal T-cell infiltrates. Interestingly, malignant T cells, in comparison with normal untransformed T cells, show a higher susceptibility toward UVAI radiation-induced apoptosis,[108] presumably because of an increased availability of caspases such as caspase-3.

PHOTOCHEMOTHERAPY

Photochemotherapy with psoralens combines the use of oral or topical psoralens (P) and ultraviolet A radiation (UVA), termed *PUVA*. Psoralens are phototoxic compounds that enter cells and then absorb photons to produce photochemical reactions that alter the function of cellular constituents.[1] This interaction results in a beneficial therapeutic effect after repeated controlled phototoxic reactions. Psoralens can be administered orally or applied topically to the skin in the form of solutions, creams, or baths. This therapy is currently used in the treatment of several common and uncommon skin diseases.

Historical Background

The effectiveness of all variants of PUVA has been widely confirmed and has profoundly influenced dermatologic therapy in general, providing treatment for numerous disorders in addition to psoriasis (Table 239-1).

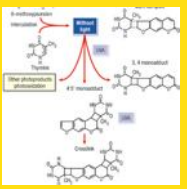
Principles of Photochemotherapy Therapy

The rationale for PUVA therapy is to induce remissions of skin diseases by repeated, controlled phototoxic reactions. These reactions occur only when psoralens are photoactivated by UVA. According to the penetration characteristics of UVA, absorption of photons is confined to the skin. However, there is also some evidence that PUVA may exert systemic effects through circulating lymphocytes affected while transiting through the skin. Clinically, PUVA-induced phototoxic reactions are characterized by a delayed sunburn-like erythema and inflammation.

PSORALENS Three psoralens are used in PUVA therapy. Methoxsalen or 8-MOP,

PHOTOCHEMOTHERAPY AND PHOTODYNAMIC THERAPY

AT A GLANCE



- Photochemotherapy [psoralen and ultraviolet A light (PUVA)] has been successfully used for more than 30 years. Its effectiveness has profoundly influenced dermatologic therapy in general, providing treatment for a number of diverse disorders besides psoriasis and vitiligo.
- PUVA can be combined with topical treatments and with some systemic agents (retinoids, methotrexate, and, perhaps, biologics) to enhance efficacy and to reduce the number of exposures.
- The most important adverse effects of oral PUVA consist of an increased risk of squamous cell carcinoma and a possible risk of melanoma. No such increased risk was found so far with bath-PUVA.
- Extracorporeal photochemotherapy (ECP) was introduced in the 1980s for the palliative treatment of erythrodermic cutaneous T-cell lymphoma.
- ECP appears to have a major impact in the treatment of graft-versus-host disease after allogeneic bone marrow transplantation where it allows progressive reduction or even discontinuation of the concomitant immunosuppressive therapy without an increase in graft-versus-host disease activity. Several other indications are under investigation.
- No serious side effects have been reported with ECP.
- Photodynamic therapy (PDT) for skin tumors started with the introduction of topical photosensitization by a porphyrin precursor (5-aminolevulinic acid) that would avoid generalized light sensitivity over many weeks.
- Current experience with PDT of epithelial cancers and pre-cancerous conditions suggests that actinic keratoses, Bowen disease, superficial and nodular basal cell carcinomas, and early squamous cell carcinomas can be treated curatively.
- The only significant side effect of topical PDT is a stinging pain during and shortly after irradiation. PDT has neither mutagenic nor carcinogenic potential.

TABLE 239-1
Phototherapy-Responsive Diseases

THERAPY OF DISEASE	PREVENTION OF DISEASE
• Psoriasis	• Polymorphous light eruption
• Palmo-plantar pustulosis	• Hydroa vacciniforme[a]
• Mycosis fungoides (stages IA, IB)	• Solar urticaria
• Vitiligo	• Erythropoietic protoporphyria[a]
• Atopic dermatitis	• Chronic actinic dermatitis[a]
• Generalized lichen planus	
• Urticaria pigmentosa	
• Cutaneous graft-versus-host disease	
• Generalized granuloma annulare	
• Pityriasis lichenoides[a]	
• Lymphomatoid papulosis[a]	
• Pityriasis rubra pilaris[a]	
• Localized scleroderma[a]	

[a]Experience limited to small number of patients.

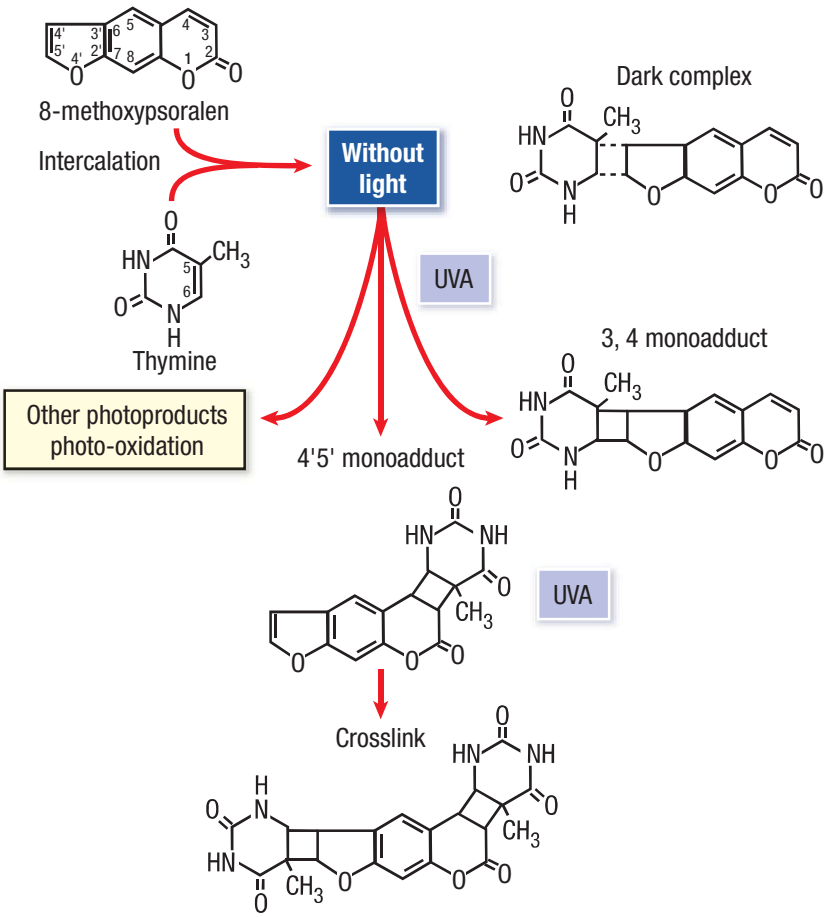
obtained from the seeds of a plant called *Ammi majus*, is most widely used and the only psoralen available in the United States. Bergapten or 5-MOP and trioxsalen (TMP) or 4, 5′, 8 trimethylpsoralen are available in Europe and elsewhere.

Psoralen Photochemistry.[5–7] Psoralens intercalate between apposing DNA base pairs in the double helix in the absence of UV radiation. Absorption of photons in the UVA range results in the formation of a 3,4- or 4,5-cyclobutane addition product (adduct) with pyrimidine bases of native DNA. In the first step of this photochemical reaction, a monofunctional adduct with thymine or cytosine is formed. Some psoralens, including 8-MOP, TMP, and 5-MOP, can absorb a second photon, and this reaction leads to the formation of a bifunctional adduct with a 5,6 double bond of the pyrimidine base of the opposite strand, thus producing an interstrand cross-link of the double helix (Fig. 239-1). This intercalation of psoralens with epidermal DNA suppresses both DNA synthesis and cell division, and it was originally assumed that this was the therapeutic mechanism in psoriasis. However, cross-linking does not appear to be a prerequisite for the therapeutic effect, and successful PUVA treatment of other skin diseases is unlikely to be directly caused by this molecular reaction; psoralens also react with RNA, proteins, and other cellular components, and indirectly modify proteins and lipids via singlet oxygen-mediated reactions or by generating free radicals.[7] Perhaps these mechanisms contribute to the effects of PUVA in diseases that are not hyperproliferative in nature.

The formation of mono- and bifunctional photoadducts in DNA results in the immediate inhibition of DNA synthesis. The interstrand cross-links are believed to be largely responsible for eliciting skin photosensitization reactions of linear psoralens such as 8-MOP. Excessive production of these cyclobutane adducts causes cell death. Mutation and skin carcinogenesis also result from photoconjugation of psoralens to DNA because the cells surviving this DNA damage tend to repair it through an error-prone repair process.

In type II reactions (see Chap. 88), reactive oxygen species ($^1O_2$, O_2 or OH) induce the oxidation of cellular lipoprotein membrane lipids and destruction of membrane-bound cytochrome P_{450}. The membrane-damaging events activate the arachidonic acid metabolism pathway, which results in an increase of secondary oxidation products that contribute to the increased synthesis of eicosanoids. Furthermore, the reactive oxygen species can directly damage DNA by generating DNA strand breaks.

Mechanisms of Photochemotherapy. Hypotheses about the mechanism of action in psoriasis are based on the known photoconjugation of psoralens to DNA with subsequent suppression of mitosis, DNA synthesis, and cell proliferation, expected to revert increased cell proliferation rates in psoriasis to normal. However, PUVA also alters the expression of cytokines and cytokine receptors, downregulates certain lymphocyte and antigen-presenting cell functions, influences adhesion molecule expression, and diminishes Langerhans cell numbers within the epidermis. In addition, PUVA affects immune effector cells



▲ **FIGURE 239-1** Psoralen photochemistry. Psoralens intercalate between apposing DNA base pairs, forming a "dark complex." Absorption of ultraviolet A (UVA) photons leads to a 3,4 or 4,5 cyclobutane monoadduct with pyrimidine bases of native DNA. The absorption of a second photon results in a bifunctional adduct producing an interstrand cross-link of the double helix.

such as lymphocytes or polymorphonuclear leukocytes. Because there is evidence that psoriasis is caused primarily by the action of blood-derived immunocytes, it is reasonable to speculate that PUVA therapy may act by affecting immune function through a direct phototoxic effect on lymphocytes in skin infiltrates. This is consistent with the observation that several other disorders that are not hyperproliferative in nature but immunomediated also respond well to PUVA. PUVA can revert pathologically altered patterns of keratinocyte differentiation and reduce the number of proliferating epidermal cells. Infiltrating lymphocytes are strongly suppressed by PUVA, with variable effects on different T-cell subsets. Lymphocytes are far more likely to undergo apoptosis than keratinocytes[8] in response to PUVA, which may explain the high efficacy in cutaneous T-cell lymphoma (CTCL), as well as in inflammatory skin diseases. Although much is known about pathways and mechanisms of psoralen photosensitization, the interactions and relative contributions to the clearing of a specific disease are not well understood.

Psoralens also stimulate melanogenesis. This involves the photoconjugation of psoralens to DNA in melanocytes, mitosis, and subsequent proliferation of melanocytes, an increased formation and melanization of melanosomes, an increased transfer of melanosomes to keratinocytes, and activation and increased synthesis of tyrosine mediated in part by stimulation of cAMP activity.

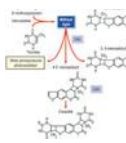
Pharmacokinetics. The important steps between the ingestion of a psoralen and its arrival at the site of action include absorption, first-pass effect, blood transportation, and tissue distribution. The absorption rate of a psoralen from the gut depends mainly on the physical characteristics of the preparation and the fat content of the concomitant food intake. Liquid preparations of 8-MOP and 5-MOP give higher and earlier peak serum levels than do crystalline formulations. In addition, peak serum levels are achieved by liquid preparations after a relatively reproducible time interval in all subjects, whereas wide time variability occurs with crystalline formulations. Before reaching the skin via the circulation, psoralens are metabolized during passage through the liver. Plasma levels of 8-MOP administered orally at different doses show a strong nonlinearity, indicating a saturable first-pass effect. The unpredictable pharmacokinetic behavior is probably due to inter- and intraindividual variations of intestinal absorption, first-pass effect, blood distribution in the body, metabolism, and elimination of the drug.

Within the same individual, serum levels of 8-MOP correspond fairly well with skin reactivity, the peak of skin phototoxicity coinciding with peak serum levels. However, phototoxic responses to PUVA show large interindividual variations. Hence, measurement of serum psoralens is a research tool and not used to monitor clinical therapy.

The pharmacokinetics of 8-MOP after topical treatment depend on the method of application. 8-MOP topically applied as a 0.15 percent emulsion or solution leads to plasma levels comparable to those found with oral treatment if large areas of the body are treated. In contrast, plasma levels after bath-PUVA treatment of almost the total body surface are very low. Bathwater-delivered psoralens are readily absorbed in the skin but are promptly eliminated without cutaneous accumulation.[8]

Ultraviolet A Radiation. UVA sources commonly used for PUVA therapy are fluorescent lamps or high-pressure metal-halide lamps. The typical fluorescent PUVA lamp has an emission peak at 352 nm and emits approximately 0.5 percent in the UVB range. UVA doses are given in J/cm^2, usually measured with a photometer with a maximum sensitivity at 350 to 360 nm. Although the action spectrum of anti-psoriatic activity and phototoxic erythema peaks at 335 nm, longer wavelengths have proved equally effective for clearing psoriasis if delivered in an adequate dose to obtain an equal erythemogenic response.[11]

Photosensitivity Effects of Photochemotherapy. PUVA treatment produces an inflammatory response that manifests as delayed phototoxic erythema, proportional to the dose of both drug and UVA as well as to the individual's sensitivity to phototoxic reactions. 8-MOP dose changes within individuals, over a narrow but clinically relevant range, appears to significantly alter the threshold for



PUVA erythema, but not the rate of increase in erythema intensity with increasing UVA dose.[10] Importantly, the time course of PUVA erythema differs from sunburn or UVB erythema that appears after 4 to 6 hours and peaks 12 to 24 hours after exposure. PUVA erythema does not appear before 24 to 36 hours and peaks at 72 to 96 hours, or even later. Hence, daily PUVA treatments can result in unexpected severe delayed cumulative phototoxicity. PUVA erythema has a shallower dose-response curve than UVB erythema (by a factor of approximately 2) and this difference is maintained even at the point of maximum erythema.[9] Severe PUVA reactions may lead to blistering and to superficial skin necrosis. Overdoses of UVA are frequently followed by swelling, intense pruritus, and, sometimes, by a stinging sensation in the affected skin area, possibly as a consequence of damage of superficial nerve endings. Erythema is at present the only available parameter that allows an assessment of the magnitude of the PUVA reaction; thus, it represents an important criterion for dose adjustments.[11]

Pigmentation is the second important effect of PUVA. It may develop without clinically evident erythema, especially when oral 5-MOP or TMP is used; this is particularly important in the treatment of vitiligo and for the preventive therapy of certain photodermatoses. In unaffected skin, PUVA pigmentation is maximal approximately 7 days after a PUVA exposure and may last from several weeks to months. As with sun-induced pigmentation, the individual's ability to tan is genetically determined, but the dose-response curve is much steeper. A few PUVA exposures result in a much deeper tan than that produced by multiple exposures to solar radiation.

TREATMENT PROTOCOLS ***Topical Treatment.*** Application of 8-MOP in creams, ointments, or lotions followed by UVA irradiation is effective in clearing psoriasis but has several disadvantages. The nonuniform distribution on the skin surface induces unpredictable phototoxic erythema reactions and irregular patches of cosmetically unacceptable hyperpigmentation. Furthermore, if numerous lesions are present, the application is laborious and time-consuming, and the treatment does not prevent the development of new active lesions in previously unaffected, untreated areas. Therefore, topical PUVA with psoralen creams, ointments, or lotions is now used only for limited plaque psoriasis and for palmo-plantar disease.

Bath Photochemotherapy. The use of bathwater delivery of psoralens provides for a uniform drug distribution over the skin surface, very low psoralen plasma levels, and rapid elimination of free psoralens from the skin. Bathwater delivery of 8-MOP circumvents gastrointestinal side effects and possible phototoxic hazards to the eyes because there is no systemic photosensitization. Skin psoralen levels are highly reproducible, and photosensitivity lasts no more than 2 hours. The higher incidence of unwanted phototoxicity can be prevented by a lower starting dose [50 percent of the minimal phototoxic dose (MPD)] and a more cautious dosimetry in the initial treatment phase. Originally, bath-PUVA was performed with TMP, but 8-MOP and 5-MOP are now being used as well. Bath-PUVA consists of 15 to 20 minutes of whole-body immersion in solutions of 0.5 to 5.0 mg 8-MOP per liter of bathwater. Irradiation needs to be performed immediately, as photosensitivity decreases rather rapidly. TMP is more phototoxic after topical application and is used at lower concentrations than 8-MOP. MPD testing for bath-PUVA must take into account that the phototoxic threshold declines during the early treatment phase,[8] in contrast to oral PUVA. Guidelines for bath, local immersion, and other topical PUVA forms have been published by the British Photodermatology Group and are based, where possible, on the results of controlled studies, or otherwise on consensus.[12]

Oral Treatment. In oral PUVA, 8-MOP is administered orally (0.6 to 0.8 mg/kg body weight) 1 to 3 hours before exposure, depending on the absorption characteristics of the particular drug brand. Liquid drug preparations are absorbed faster and yield higher and more reproducible serum levels than microcrystalline forms. For 5-MOP, the usual dosage is 1.2 to 1.8 mg/kg body weight.

The initial UVA doses are determined by either the patient's skin type[13,14] or MPD testing.[11,15] The MPD is defined as the minimal dose of UVA that produces a barely perceptible, but well-defined, erythema when template areas of the skin are exposed to increasing doses of UVA. Erythema readings are performed 72 hours after testing, at which time the psoralen phototoxicity reaction usually reaches its peak. The MPD test should be performed on previously non-exposed skin (e.g., buttocks). Although the MPD test is more time-consuming than phototyping, it allows for more accurate and higher UVA doses during initial treatment. Table 239-2 shows recommendations for dosimetry in bath and oral PUVA.

Repeated exposures are required to clear PUVA-responsive diseases, with gradual dose increments as pigmentation develops. Lower doses quite frequently result in failure of treatment except in those diseases in which induction of pigmentation is the desired objective. In most dermatoses amenable to PUVA, the frequency of treatments is reduced after satisfactory clearing of disease, and the last UVA dose is used as a maintenance dose, if maintenance treatment is planned. The duration of this maintenance phase and the frequency of treatments depend on the particular disease being treated and its propensity to relapse.

Indications for Photochemotherapy

PHOTOCHEMOTHERAPY FOR PSORIASIS Basically all types of psoriasis respond to PUVA (Figs. 239-2 and 239-3), although the management of erythrodermic or generalized pustular psoriasis is more

TABLE 239-2
Recommended Treatment Schedule for Photochemotherapy

1	Determination of MPD	Reading	After 96–120 h (bath-PUVA) After 72–96 h (oral PUVA)
2	Start of treatment	First therapeutic dose	30% of MPD (bath-PUVA) 50%–70% of MPD (oral PUVA)
3	Treatments two to four times weekly	No erythema, good response	Increase once weekly by 30%
		No erythema, no response	Increase by 30%
		Minimal erythema	No increase
		Persistent asymptomatic erythema	No increase
		Painful erythema (with or without blistering)	No treatment until symptoms subside
4	Resumption of treatment	After resolution of symptoms	Reduction of last dose by 50%, next increase by 10%

MPD = minimal phototoxic dose; PUVA = psoralen and ultraviolet A light.

◀ **FIGURE 239-2** Twenty-three-year-old patient with generalized psoriasis (seborrheic type). **A.** Before photochemotherapy treatment. **B.** After treatment. (From Wolff K et al: Photochemotherapie bei Psoriasis. Klinische Erfahrungen bei 152 Patienten. *Dtsch Med Wochenschr* **100**:2471, 1975 with permission.)

difficult.[2] The effectiveness of oral PUVA in inducing and maintaining remission of psoriasis has been widely documented and confirmed by large-scale clinical trials (see Figs. 239-2 and 239-3).

Administration. Three studies have compared bathwater delivery of 8-MOP with oral administration. In two reports, initial doses were determined by skin typing, and treatments were given two to three times weekly. Dose increments were instituted with every treatment in one study, whereas smaller increments were given every third treatment in the other. The third report, in which patients were treated according to the standard European regimen for oral PUVA, showed the lowest incidence of treatment failures and overdose phenomena. Compared with oral 8-MOP, bath-PUVA showed equal clearing rates with fewer exposures.[8] The greater therapeutic efficacy could be because of a higher penetration of psoralens through the abnormal stratum corneum overlying psoriatic plaques, as compared with healthy perilesional skin where phototoxicity is monitored during the therapy. The incidences of erythema and pruritus were similar or lower compared with oral therapy. Systemic intolerance, such as nausea and vomiting, were not observed.

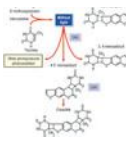
Oral 5-MOP–PUVA represents an alternative to oral 8-MOP–PUVA. Psoriatic lesions are cleared with a comparable number of treatments, but at the expense of significantly higher cumulative UVA doses. This difference may be due to the lower phototoxicity potential of 5-MOP and of its higher tanning activity. However, 5-MOP–PUVA therapy is not associated with nausea and vomiting and has a lower incidence of pruritus and severe phototoxic erythema.[8]

On complete clearing, patients are often assigned to maintenance therapy, during which the frequency of treatments is gradually reduced. The purpose of maintenance therapy is to achieve longer remission. Maintenance therapy in the original European regimen consisted of 1 month of twice-weekly treatments, with the last UVA dose used for clearing, followed by another month of once-weekly exposures. According to other recommendations,[16] maintenance treatment should be considered only on rapid relapses, because patients with a stable remission may be over-treated, and long-term risks of PUVA are related to the total cumulative phototoxic doses. In one left–right comparison study with psoriatics, PUVA maintenance treatment over 2 months did not increase the length of remission.

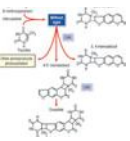
Erythrodermic and generalized pustular psoriasis (von Zumbusch type) respond to PUVA (Fig. 239-4), but the time required to induce remission is considerably longer, more treatments are needed, and higher failure rates are reported, compared with plaque or guttate varieties. Pustular eruptions of palms and soles are quite recalcitrant to treatment, regardless of whether they are true localized pustular psoriasis, nonpsoriatic palmo-plantar pustulosis or pustular psoriasis, or pustular eczema. Oral PUVA alone can produce a slow but definite remission in many cases, but a considerable number of patients require adjunctive therapy for clearing. As mentioned above, the combination with topically applied 8-MOP can be beneficial, but bath-PUVA appears to be also quite effective in such cases.

PUVA alone can produce definite remissions in many patients with psoriasis, but a considerable number require additional therapies for clearing. Such combination therapy (see the section Combination Treatments) improves efficacy and reduces possible side effects.

▲ **FIGURE 239-3** Twenty-three-year-old patient with generalized psoriasis (plaque-type). **A.** Before photochemotherapy treatment. **B.** After treatment. (From Wolff K, Hönigsmann H: Clinical aspects of photochemotherapy. *Pharmacol Ther* **12**:381, 1981 with permission.)



▲ **FIGURE 239-4** Eighteen-year-old patient with pustular psoriasis (von Zumbusch type). **A.** Before photochemotherapy treatment. **B.** After treatment. (From Hönigsmann H et al: Photochemotherapy for pustular psoriasis (von Zumbusch). *Br J Dermatol* **97**:119, 1977, with permission.)



Combination Treatments. **TOPICAL COMBINATIONS.** Topical adjuvant therapies with glucocorticoids, anthralin, and tar preparations, and, more recently, with calcipotriol and tazarotene, have yielded good results. However, adjunctive topical therapy is found unacceptable by some patients because it is considered a step backward to conventional treatment.

METHOTREXATE. A combination of PUVA and methotrexate can reduce the duration of treatment, number of exposures, and total UVA dose and is also effective in clearing patients unresponsive to PUVA or UVB alone.[17] This combination appears to be safe if used during the clearing phase only. However, if used for long-term treatment, PUVA and methotrexate may act synergistically in the development of skin cancers.[18]

CYCLOSPORINE. Cyclosporine plus PUVA dramatically enhances skin carcinogenesis. This is in keeping with the observation of a greatly increased risk of cutaneous squamous cell carcinomas in patients with solid organ transplants maintained on this immunosuppressant. Thus, this combination should be definitely discouraged.[8,19–21]

RETINOIDS. The therapeutic efficacy of PUVA therapy is dramatically increased by daily oral retinoid (etretinate, acitretin, isotretinoin; 1 mg/kg) administration beginning 5 to 10 days before the initiation of PUVA, and continued throughout the clearing phase. This so-called *RePUVA* characteristically reduces the number of exposures by one-third and the total cumulative UVA dose by more than one-half. RePUVA also often clears "poor responders" who are not brought into complete remission by PUVA alone.[22]

The mechanism of the synergistic action of retinoids and PUVA is unknown, but may be a result of the accelerated desquamation that optimizes the optical properties of the skin and reduction of the inflammatory infiltrate. As an additional beneficial effect, etretinate and other retinoids may theoretically protect against long-term carcinogenic effects of PUVA. In one study, patients with psoriasis treated with PUVA in combination with systemic retinoids showed a reduced risk of squamous cell carcinoma but not a significantly altered incidence of basal cell carcinoma (BCC).[23] Although retinoid toxicity is generally not a concern because the administration is limited to the clearing phase, the potential teratogenicity of retinoids represents a serious concern for women of child-bearing age. In these patients, the use of isotretinoin is advisable because contraception is necessary for only 1 month after discontinuation of therapy, in contrast to etretinate and acitretin, which require 2 years of contraception because of their slower elimination.[8]

BIOLOGICS. The mechanism of action of biologic agents suggests that there may be additive effects in treating psoriasis with PUVA, but this remains to be further defined in clinical trials.[24,25]

PUVA FOR CUTANEOUS T-CELL LYMPHOMA (MYCOSIS FUNGOIDES) Since the first promising results with PUVA in CTCL in 1976,[26] numerous investigators from the United States and Europe have confirmed the efficacy of PUVA for CTCL.[27] Treatment schedules and dosimetry are essentially the same as for psoriasis. The treatment consists of a clearing phase (Fig. 239-5), a maintenance phase consisting of two exposures per week for 1 month and one exposure per week for another month, and a follow-up phase without therapy. Remission should be confirmed by histologic examination of previously involved skin sites. After therapy is discontinued, the patient is moni-

▲ **FIGURE 239-5** Forty-six-year-old patient with cutaneous T-cell lymphoma (mycosis fungoides), stage IB. **A.** Before photochemotherapy treatment. **B.** After treatment (clearing phase).

tored monthly and later bimonthly. If a relapse occurs, the patient is again subjected to a full PUVA course. Some investigators advocate permanent maintenance treatment consisting of treatments once monthly or every other month. However, the course of CTCL varies considerably from patient to patient, and clinical experience suggests that patients benefit most from individualized treatment schedules.[8]

Relapses respond as well as the initial lesions when PUVA is resumed. Clinical remissions appear to be directly related to phototoxic destruction of the malignant lymphocytes that infiltrate the skin. Thus, complete clearing may be induced when the cells are confined to the epidermis and superficial dermis, the depth of effective UVA penetration into the skin.

Present knowledge indicates that PUVA is an excellent treatment option that may induce long-lasting disease-free intervals in CTCL if used in the early stages of the disease.[27] In later stages, PUVA may reduce the tumor cell burden and thus may act synergistically with other treatment. It improves quality of life and may prolong survival when used in combination with more aggressive treatment modalities. Prolonged remissions were observed with combinations of PUVA with retinoids, bexarotene,[28,29] or interferon-α 2a.[30,31]

Patients with tumor-stage CTCL exhibit a high rate of early recurrences and therefore require indefinite maintenance treatment. PUVA causes complete tumor resolution only when used in combination with local x-ray treatment and/or systemic chemotherapy. Most follow-up studies have demonstrated that the great majority of patients with early disease can be kept in remission with or without maintenance therapy for several years, but tumor-stage patients (IIB) usually experience multiple recurrences despite aggressive combination therapies and eventually die within a few years.[27] Currently, no therapeutic regimen is known to arrest the eventual progression of CTCL to tumor formation, dissemination, and fatal outcome. Although PUVA therapy is very effective in inducing remission as long as the lymphoma is clinically confined to the skin, the influence of this therapy on the natural course of CTCL and on patient survival has not been determined. However, data from the Swedish National Central Bureau of Statistics show a significant drop in the death rate of patients since the introduction of PUVA.[32]

Successful treatment of erythrodermic CTCL (Sézary syndrome) has been reported with extracorporeal PUVA (photopheresis) [see Extracorporeal Photochemotherapy (Photopheresis)]. Possible long-term hazards related to frequent PUVA treatments are of less concern for patients with CTCL, compared with patients with benign conditions.

PHOTOTHERAPY FOR ATOPIC DERMATITIS Many patients with atopic eczema can benefit from PUVA therapy.[33] The treatment guidelines are the same as for psoriasis. However, the condition is more difficult to treat, and quite often a higher number of treatments are required to clear the eczema. There is a high and early recurrence rate, requiring frequent maintenance exposures. A combination of PUVA with topical glucocorticoids appears to be superior to PUVA alone in maintaining remissions. Because the average patient is young, long-term maintenance therapy is problematic; and combination of PUVA with topical immune modulators (tacrolimus, pimecrolimus), although effective, cannot be recommended until more data are available. The mechanism of action of PUVA in atopic eczema is unclear; current concepts support an alteration of lymphocytes in the dermal infiltrate.

PHOTOTHERAPY FOR LICHEN PLANUS In generalized lichen planus, PUVA can provide an effective alternative to systemic glucocorticoid treatment, although it appears to be more resistant to PUVA than psoriasis when treated according to a similar schedule. More exposures and higher cumulative UVA doses are required for clearing, and not all patients respond satisfactorily. An exacerbation during PUVA treatment has been reported in a few patients. In patients who clear, relapses respond equally well when PUVA is resumed. Bath-PUVA can also clear lichen planus, and combined PUVA-etretinate regimen may be considered.[34]

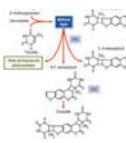
PHOTOCHEMOTHERAPY FOR CUTANEOUS MASTOCYTOSIS In cutaneous mastocytosis (urticaria pigmentosa), PUVA leads to a temporary involution of skin lesions,[35] probably due to chronic degranulation of the mast cells. The treatment results in loss of Darier's sign, relief of itching, and flattening and even complete disappearance of cutaneous papules and macules. Surprisingly, even systemic symptoms such as histamine-induced migraine and flushing improve gradually as treatment is continued.[35] In most patients, the manifestations of the disease recur several months after discontinuation of PUVA, but the recurrences respond as well as the original lesions.

Because treatment of cutaneous mastocytosis has been unrewarding with other modalities, the use of PUVA, although not curative, seems to be warranted in patients when the disease is causing severe distress.

PHOTOTHERAPY FOR MISCELLANEOUS DERMATOSES Both acute and chronic pityriasis lichenoides[34] respond to PUVA, and favorable results have been reported for lymphomatoid papulosis.[36] However, the experience with these conditions is limited to a few anecdotal cases. In pityriasis rubra pilaris, the results are quite inconsistent. Some cases seem to respond well, others may flare, and some require combination treatment with retinoid or methotrexate therapy. Generalized granuloma annulare has been reported to clear completely, but long-term maintenance treatment was required to maintain remissions.[37] Regrowth of hair was noted in alopecia areata with either topical or systemic PUVA exposures localized to the alopecia areas. Follow-up studies of larger patient groups concluded that PUVA is generally not an effective treatment for alopecia areata.[38] The experience of the present authors has also not been encouraging. Localized scleroderma and pansclerotic morphea have been successfully treated with bath-PUVA and oral PUVA.[39,40]

PHOTOCHEMOTHERAPY FOR CHRONIC GRAFT-VERSUS-HOST DISEASE Acute and chronic cutaneous graft-versus-host disease (GVHD) have become indications of increasing importance. Because of the clinical and histologic similarities of idiopathic lichen planus and lichenoid GVHD, PUVA treatment was evaluated for the latter.[41] PUVA cleared or improved this lichen planus–like eruption in patients who had not responded to conventional immunosuppressive therapy alone. PUVA can also improve acute GVHD,[42] although results of PUVA treatment for scleroderma-like variants of cutaneous GVHD are controversial. According to our own experience, the more circumscribed, localized forms appear to respond to PUVA with softening of the fibrotic, sclerotic connective tissue, but more widespread, disseminated lesions hardly respond.

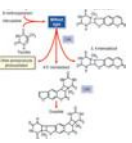
Improvement of mucosal erosions followed by healing, observed during treatment of chronic lichenoid GVHD



with PUVA, suggests that PUVA may exert both local and systemic effects, but this is not proven. There is no improvement of GVHD of other organs, such as the liver.

The therapeutic regimen used for the treatment of chronic GVHD is basically the same as for psoriasis. UVA doses should not be increased too aggressively, to avoid erythema and possible (re)activation of GVHD. In general, increase of the UVA dosage by 0.5 J/cm^2 at maximum after every second to fourth exposure is recommended. Patients are exposed to UVA radiation three to four times weekly. After clearing of skin lesions, the frequency of exposures is reduced.

There appears to be an overall increased risk of secondary malignancies for all bone marrow/peripheral stem cell recipients, and they should be examined on a regular basis for the development of cutaneous malignancies, independent of whether they had experienced cutaneous GVHD or had been treated with PUVA.



PHOTOCHEMOTHERAPY FOR VITILIGO Vitiligo was the first disease treated with an ancient form of psoralen PUVA in India and Egypt. PUVA in its modern form stimulates melanogenesis, melanocyte proliferation and migration, and reconstitutes the normal skin color in more than 50 percent of vitiligo patients. However, it is less used now since narrowband UVB phototherapy has been shown to be effective and possibly safer alternative for repigmentation of this condition.

To induce maximal repigmentation, patients need long-term therapy with 100 to 200 exposures given twice or thrice weekly. Approximately 70 percent of patients respond after 12 to 24 months (Fig. 239-6), as defined as the development of perifollicular macules of repigmentation. If there is no response after 6 months or approximately 50 treatments (as defined as perifollicular macules of repigmentation), PUVA should be terminated. If treatment is discontinued, this newly acquired repigmentation may be lost. Completely repigmented areas are often stable for a decade or more without relapse.[43]

Patient selection appears to be particularly important in vitiligo treatment. Lips, distal dorsal hands, tips of fingers and toes, areas of bony prominences, palms, soles, and nipples are very refractory to treatment, and patients with involvement limited to these areas should be excluded. Segmental vitiligo tends to show a variable response. Because of the different response in different body areas, total repigmentation is only rarely achieved, and some 30 percent of patients do not respond at all despite many months of therapy. Duration of the disease before PUVA therapy does not affect response rate.

▲ **FIGURE 239-6** Twelve-year-old patient with generalized vitiligo of 4 years' duration. **A,C.** During the initial phases of photochemotherapy treatment. **B,D.** 1 month after treatment (8-methoxypsoralen + artificial ultraviolet A) with thrice-weekly exposures for 10 months.

The mechanisms by which PUVA induces repigmentation in vitiligo skin are speculative. However, PUVA's known effect on a number of immunologic reactions suggests a suppression of the autoimmune stimulus for melanocyte destruction.

PHOTOCHEMOTHERAPY AS PREVENTION FOR PHOTODERMATOSES Tolerance to sunlight can be induced in several photodermatoses with PUVA. In polymorphous light eruption, the most common photodermatosis, PUVA is the most effective preventive treatment.[44] In approximately 70 percent of patients with this condition, a 3- to 4-week PUVA course of two to three treatments per week suffices to suppress the disease on subsequent exposure to sunlight. The initial exposure and dose increments during therapy should be performed according to the guidelines outlined for psoriasis. PUVA has the advantage of a rapid and intense pigment induction at relatively low UVA doses that usually remain well below the threshold doses for eliciting the rash. Approximately 10 percent of patients develop typical lesions during the initial phase of PUVA, but these usually disappear when treatment is continued. The authors' treatment schedule consists of three to four treatments per week for 3 to 4 weeks in early spring. PUVA protects only temporarily, but subsequent sun exposures usually maintain protection and many patients remain protected for 2 to 3 months even after their pigmentation has faded.

The mechanism by which phototherapy induces tolerance to sunlight is not clear. Hyperpigmentation and thickening of the stratum corneum may be important factors, but other mechanisms, such as modulations of cutaneous immune functions, may also be involved.[44]

There is also some experience with PUVA prophylaxis of other photodermatoses. In solar urticaria, PUVA therapy appears to be the most effective preventive treatment available and is certainly better than antihistamines. Tolerance to sunlight can be increased 10-fold or more

after a single treatment course. The suppressive effect may last throughout the summer if the patients have regular sunlight exposures, which seems to be necessary to maintain tolerance. Problems may arise during the first PUVA exposures, because, in some patients, the urticaria threshold dose is very low. In these cases, careful conditioning by stepwise UVA irradiation of single quadrants of the body surface a few hours before each PUVA treatment have proved useful. Treatments with PUVA are then given during the refractory period of presumed mast cell degranulation.

Successful PUVA has also been reported in occasional cases of chronic actinic dermatitis and hydroa vacciniforme. Limited experience in patients with erythropoietic protoporphyria indicates that, with a very cautious approach and in combination with β-carotene, PUVA may increase light tolerance considerably.[45,46]

Extended treatment is usually not required in polymorphous light eruption but may be necessary in solar urticaria and chronic actinic dermatitis. There exist no ready-to-use schedules for these latter conditions, and PUVA is usually just one part of the management.[45]

PHOTOCHEMOTHERAPY IN HUMAN IMMUNODEFICIENCY VIRUS–INFECTED PATIENTS

The use of phototherapy and PUVA in human immunodeficiency virus (HIV)–infected patients with skin diseases is controversial. Both therapies can induce systemic immune suppression and may modify the immune status of the patient in a way that would worsen HIV disease.[47] Both UV radiation and psoralen photosensitization activate the HIV promoter, which could boost viral gene transcription and, eventually, virus production,[48] although available data and theoretic considerations indicate that UVB is more likely to be a hazard than PUVA in an HIV-infected population.[51,52] Nevertheless, oral PUVA treatment of psoriasis does not detectably accelerate progression of HIV disease or increase side effects,[49,50] and was concluded that PUVA is not contraindicated for HIV-positive patients with responsive skin diseases.

Side Effects and Toxicity of Photochemotherapy (Table 239-3)

TABLE 239-3
Side Effects and Toxicity of Photochemotherapy

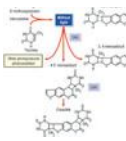
Acute side effects	
Drug intolerance	Nausea, vomiting with oral MOP, but not with 5-MOP.
UVA overdosage	Can range from an increased delayed erythema reaction to severe burns with blistering. When large areas of skin are affected, systemic symptoms of excess phototoxicity, such as fever and general malaise, can occur.
Pruritus	Some patients experience persistent pruritus during photochemotherapy (PUVA) treatment, particularly after slight UVA overdosage.
Laboratory data	No significant abnormal findings in patients receiving PUVA over prolonged periods of time.
Potential long-term risks	
Chronic actinic damage	Chronic exposure to PUVA may produce changes in the skin that resemble photoaging. PUVA lentigines and generalized PUVA lentiginosis result from repeated and prolonged treatment and are commonly associated with high cumulative doses of UVA and a large number of treatments. So far, no increased risk of cutaneous melanoma associated with these lentigines has been recorded.
Carcinogenesis	The risk of squamous cell carcinoma, but not of basal cell carcinoma, is significantly increased in comparison with matched controls, and the magnitude of the increase appears to be dose-dependent. There is still uncertainty about PUVA being the sole factor—many of the affected patients had previous exposure to excessive sunlight and to treatments with carcinogenic potential, including arsenic, UVB, cyclosporine, and antimetabolite therapy. No increased risk was found so far with bath-PUVA.
Melanoma	Stern et al. reported from patients enrolled in the PUVA Follow-up Study (16-Center Study[63]) that, beginning 15 years after first exposure to PUVA, an increased risk of melanoma was observed. This risk was greater in patients exposed to high doses of PUVA and appeared to be increasing with the passage of time. The conclusions of this study have been questioned, and the authors now agree that the observed risk of melanoma does not represent an absolute contraindication to PUVA or that PUVA therapy should be abandoned. Rather, the risks of both melanoma and squamous cell carcinoma in PUVA should be weighed against the substantial efficacy of PUVA and the risks of other therapies.
Ophthalmologic effects	Several studies have shown no indication that psoralen-induced cataracts occur in patients undergoing long-term photochemotherapy, even in patients who neglected eye protection.

MOP = 8-methoxypsoralen; PUVA = psoralen and ultraviolet A light.

ACUTE SIDE EFFECTS The side effects of PUVA include drug intolerance reactions as well as side effects of the combined action of psoralens plus UVA radiation. Oral 8-MOP (0.6 to 0.8 mg/kg) has a high incidence of nausea (30 percent of patients) and vomiting (10 percent of patients), and this may occasionally require discontinuation of the treatment. These side effects are more common with liquid preparations than with crystalline preparations, probably because of higher psoralen serum levels. With 5-MOP, nausea is almost absent, even with doses of up to 1.8 mg/kg body weight.

Undesired acute effects of the combined action of psoralens and UVA can range from an increased delayed erythema reaction to severe burns with blistering. When large areas of skin are affected, systemic symptoms of excess phototoxicity, such as fever and general malaise, may occur. Nonsteroidal anti-inflammatory drugs and topical and systemic corticosteroids may be required to alleviate the symptoms but have to be given early. Some patients experience persistent pruritus during PUVA treatment, particularly after slight UVA overdosage, and, in rare cases, a stinging pain may develop in circumscribed areas. The mechanism is unknown, and the symptoms are unresponsive to antihistamines. These complaints usually subside on continuation of treatment. Overdosage phenomena occur mostly in body areas not usually exposed to natural sunlight. Careful observation of the criteria for dosimetry can minimize these side effects to acceptable levels. The danger of overdosage is much less with 5-MOP.

Very rare side effects of PUVA include polymorphous light eruption-like rashes, acne-like eruptions, subungual hemorrhages caused by phototoxic reactions in the nail beds, and occasional hypertrichosis of the face. These disappear when treatment is discontinued. Single case re-



ports note exacerbation of systemic lupus erythematosus and bullous pemphigoid during PUVA.

LABORATORY DATA Analysis of laboratory data in several large-scale studies showed no significant abnormal findings in patients receiving PUVA over prolonged periods of time.[13,14,53] Serial laboratory examinations performed over a period of several years have not revealed any substantial evidence for impairment of hepatic function. Liver biopsies after 1 year of therapy did not reveal hepatotoxicity.[54] No evidence exists suggesting impairment of renal function.[13] Several large-scale studies have negated a suggested relation between PUVA therapy and the occurrence of anti-nuclear antibodies.[55]

POTENTIAL LONG-TERM RISKS OF PHOTOCHEMOTHERAPY ***Chronic Actinic Damage.*** Repeated photodamage to the skin can be expected to result in cumulative injury regardless of whether it is induced by sunlight, artificial UV radiation, or PUVA. Chronic exposure to PUVA may produce changes that resemble photoaging and that may add to the injury induced by sunlight.

PUVA lentigines and generalized PUVA lentiginosis result from repeated and prolonged treatment and are commonly associated with high cumulative doses of UVA and a large number of treatments.[14] The lentigines exhibit irregular borders and uneven pigmentation. No increased risk of cutaneous melanoma has been associated with these lentigines, but the cosmetic effect may be quite disturbing.

Carcinogenesis. Cutaneous carcinogenicity is the major concern for long-term PUVA treatment associated with high cumulative UVA doses. PUVA is a photocarcinogen (see Chap. 112). In laboratory animals, 8-MOP and 5-MOP have been unequivocally shown to induce skin cancer at levels of drug and UVA irradiation comparable to those used in PUVA therapy.[56,57] However, this risk is related to DNA damage, but PUVA-induced downregulation of immune responses may play an additional role. This risk has to be assessed against the potential therapeutic benefit.

Long-term follow-up PUVA studies are confounded by the fact that patients, particularly those with severe psoriasis, are likely to have been exposed previously to other carcinogenic treatments, such as ionizing radiation, UVB therapy, methotrexate, tar, or arsenic, and accurate exposure data are often lacking.

In PUVA patients, the risk of squamous cell carcinoma, but not of BCC, is significantly increased in comparison with matched controls and the magnitude of the increase appears to be dose-dependent.[18,57] However, there is uncertainty about PUVA being the sole factor—many of the affected patients had previous exposure to excessive sunlight and to treatments with carcinogenic potential, including arsenic, UVB, and antimetabolite therapy.[58] Particularly, high levels of UVB exposure appear to increase the risk of non-melanoma skin cancer in PUVA-treated patients.[59] According to one study, the genitalia in man previously treated with tar and UVB appeared to be particularly susceptible to PUVA carcinogenesis,[60] but the risk seemed not to be increased if only PUVA was used.[61] In a retrospective study from France comprising 5400 patients treated with PUVA between 1978 and 1998, no case of genital skin cancer was found, despite the fact that the genital area had not been protected.[62] This makes it unlikely that genital shielding is absolutely necessary.

Carcinogenicity of 5-MOP–UVA therapy in PUVA-treated patients is not documented, but 5-MOP has shown mutagenicity similar to 8-MOP in model systems.

Stern et al. reported that of the cohort of 1380 patients enrolled in the so-called *16 Center PUVA Follow-up Study,* 23 patients have developed 26 invasive or in situ cutaneous melanomas over a period of roughly 25 years. Beginning 15 years after first exposure to PUVA, this constituted an increased risk of melanoma.[63,64] This risk was greater in patients exposed to high doses of PUVA and appeared to increase with the passage of time. The conclusions of this study have been questioned,[65] and the authors now agree[64] that the observed risk of melanoma does not represent an absolute contraindication to PUVA. Rather, the risks of both melanoma and squamous cell carcinoma in PUVA should be weighed against the substantial efficacy of PUVA and the risks of other therapies.[65] Of note, PUVA's long-term risks have been subject to much greater scrutiny than the risks of other therapies advocated for severe psoriasis, such as methotrexate and, particularly, immunosuppressive therapies such as cyclosporine. These latter therapies greatly increase cancer risk in populations less likely to have substantial exposures to known cutaneous carcinogens such as UVB than are patients with severe psoriasis. Early detection through careful, long-term follow-up and education of PUVA patients may reduce the long-term morbidity and mortality associated with this therapy, as can low cumulative dosage regimens.[66]

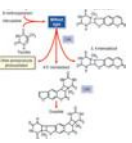
Studies of 944 Swedish and Finnish patients[67] and 158 Finnish patients[68] with psoriasis showing no association between cutaneous cancer and TMP or 8-MOP bath-PUVA, respectively, are reassuring. UVB is carcinogenic, but mathematic model studies indicate that the observed risk of squamous cell carcinoma is much higher with PUVA than with UVB.[69] The carcinogenic risk of narrowband UVB in comparison with PUVA is unknown, and it will be crucial to monitor its long-term effects in psoriatics.

Ophthalmologic Effects. Data from animal studies indicate a risk of premature cataract formation due to PUVA, but clinical evaluation suggests no increase in lens opacities, even in patients who neglect careful eye protection during long-term PUVA.[70]

Patient Selection and Contraindications

In view of the potential long-term hazards of PUVA, the assignment of patients should be based on consideration of the risks and the benefit for the individual patient. If only a short-term course of therapy is planned, as, for example, in prevention of photodermatoses, the benefit outweighs the risk. In the treatment of a malignant condition such as CTCL, long-term risks may be discounted because other treatment options bear even greater long-term risks. The major concerns relate to long-term treatment of psoriasis, by far the most common indication for PUVA. Careful patient selection appears to be mandatory, bearing in mind that long-term risks of alternative therapies may simply be less well documented rather than less. Guidelines have been published.[15]

PUVA is not recommended during pregnancy, and women should be advised to use contraceptive measures while on PUVA. This precaution is only for reasons of absolute safety as there exists no evidence that either 8-MOP alone or PUVA is teratogenic, as confirmed in a retrospective study in 256 deliveries among the cohort of the 16-Center



PUVA Follow-Up Study.[71] However, it has to be emphasized that RePUVA bears the risk of retinoid teratogenicity.

Severe impairment of hepatic and renal functions is usually considered a contraindication to PUVA because metabolism and excretion of psoralens may be inadequate. PUVA is also contraindicated in patients with known light-aggravated or light-induced diseases such as lupus erythematosus, porphyria (but, as mentioned above, light tolerance can be induced by PUVA in erythropoietic protoporphyria), and xeroderma pigmentosum. Pemphigus vulgaris and bullous pemphigoid may be exacerbated by PUVA. Patients with chronic actinic damage and a history of skin cancers may be at higher risk for the development of new cancers. Previous arsenic intake and previous treatment with ionizing radiation also seem to increase the risk of non-melanoma skin cancers. Immunosuppressed patients should probably not receive PUVA, although this is not yet clearly defined. As outlined above, PUVA can be used in HIV-positive patients. Cataracts and aphakia are not contraindications if adequate eye protection is guaranteed.

Conclusions and Perspectives

PUVA is a highly effective treatment for several dermatologic diseases. Although there exists comprehensive clinical experience documenting PUVA's short-term safety when used according to standardized methods, potential long-term sequelae have still not been clearly determined. Thus, treatment decisions should take into account whether other equally effective forms of therapy that carry a lower risk are available. Risk-versus-benefit varies with the disease being treated.

Severe widespread psoriasis is a devastating disease that may result in disruption of professional, social, and private life. After more than three decades of experience with PUVA for the treatment of psoriasis, it is evident that this therapy offers innumerable patients the chance to resume a normal life. For disabling psoriasis, the choice of therapies lies not between risk and safety but among modalities (methotrexate, cyclosporine, UVB, and biologics), none of which is absolutely safe.[65]

EXTRACORPOREAL PHOTOCHEMOTHERAPY (PHOTOPHERESIS)

Extracorporeal PUVA (ECP) was introduced in the 1980s for the palliative treatment of erythrodermic CTCL,[72] a disorder characterized by circulating malignant lymphocytes. Its efficacy was subsequently confirmed by several clinical trials and approved in 1988 by the U.S. Food and Drug Administration for this indication. At the International Consensus Conference on Staging and Treatment Recommendations for CTCL in 1994[73] and at the European Organization for Research and Treatment of Cancer Consensus Recommendations in 2006,[74] ECP was recommended as the first line of treatment for patients with erythrodermic CTCL.

Attempts to better characterize those CTCL patients likely to respond to ECP revealed a significant linear association between response and CD4:CD8 ratio. Patients with a ratio less than 10 are more likely to respond than patients with a ratio greater than 10. There is also a marginally significant linear association between response and lactic acid dehydrogenase (LDH) level, with patients whose LDH is not elevated at the start of treatment responding better than patients with an elevated LDH.[75]

Treatment Method

ECP involves the oral administration of 8-MOP followed by phlebotomy at the time of peak photosensitization passage of blood fractions from one arm vein through a photopheresis machine and back. A discontinuous flow cell separator harvests peripheral blood mononuclear cells (PBMCs) in a buffy coat collection and returns the red cell fraction to the patient without further treatment. The collection of PBMC is then exposed to 2.0 J/cm^2 of UVA using a photopheresis device that assures exposure of individual PBMC in a thin film to the light source and then reinfused into the patient. Alternatively, 8-MOP can also be administered directly to the heparinized plasma and buffy coat fraction as it flows through an UVA exposure system, thereby avoiding 8-MOP–induced nausea and unintended phototoxicity with subsequent incidental sun exposure. This treatment is, on average, repeated on 2 successive days at 2- to 4-week intervals.

Mechanism of Action

The mode of action of ECP remains unknown. The PUVA exposures likely induce apoptosis of circulating malignant lymphocytes. However, it has also been shown that infusion of autologous haptenated cells in which apoptosis had been initiated by 8-MOP/UVA induces immunologic tolerance. This tolerance is due primarily to regulatory T cells because transfer can be achieved in an animal model. Induction of regulatory T cells could explain why ECP exerts a beneficial effect in a wide variety of immune-mediated diseases and why generalized immunosuppression does not occur with ECP.[76]

Side Effects

No serious side effects have been reported with ECP. With oral ingestion of 8-MOP, transient nausea is not uncommon (as in oral PUVA therapy) and, rarely, episodes of hypotension and vasovagal reflex due to volume shifts during treatments have been noted. However, these events usually do not interfere with the treatment.

Treatment Results

CUTANEOUS T-CELL LYMPHOMA Erythrodermic CTCL (Sézary syndrome) was the first disease for which ECP was evaluated. A response occurs in up to 75 percent of the patients, with complete remissions in up to 25 percent. In Sézary syndrome patients who do not sufficiently respond to ECP alone, ongoing studies are evaluating possible synergistic effects with other treatments such as interferon-α, methotrexate, bexarotene, and total-skin electron-beam therapy.[77–80]

GRAFT-VERSUS-HOST DISEASE AND ALLOGRAFT REJECTION ECP appears to have a major impact in the treatment of GVHD after allogeneic bone marrow transplantation.[81,82] In patients with either acute or chronic GVHD, ECP allows reduction or even discontinuation of immunosuppressive therapy without an increase in GVHD activity. ECP is especially useful for patients affected by GVHD resistant to conventional treatment.

In addition, ECP is effective in the treatment of acute allograft rejection among lung, cardiac, and renal transplant recipients. ECP is effective for patients resistant to conventional treatments, particularly if started early. Benefit is obtained without the complications typically encountered with immunosuppressive regimens used to control organ rejection.[83,84] Table 239-4 shows indications for photopheresis as currently seen by regulatory agencies.

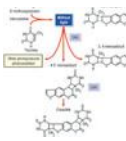


TABLE 239-4
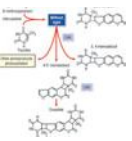
Indications for Photopheresis (As Seen by Regulatory Agencies in 2006)

Sufficient evidence available	
Erythrodermic cutaneous T-cell lymphoma	Chronic graft-versus-host disease
Acute graft-versus-host disease	Organ transplant rejection
Experimental and investigational	
Scleroderma	Nephrogenic fibrosing dermopathy
Bullous dermatoses	Lichen planus
Crohn disease	Multiple sclerosis



PHOTODYNAMIC THERAPY

Photodynamic therapy (PDT) aims to destroy the desired target selectively, thereby minimizing damage to normal tissue. The photodynamic reaction consists of the excitation of photosensitizers (usually porphyrins) by visible light in the presence of oxygen, resulting in the generation of reactive oxygen species, particularly singlet oxygen. These reactive oxygen species mediate cellular and vascular effects, depending on the tissue localization of the photosensitizer, and results in a direct or indirect cytotoxic effect on the target cells.[86] In dermatology, PDT has been used effectively for pre-cancerous and malignant conditions such as actinic keratosis, BCC, Bowen disease, and superficial squamous cell carcinoma, as well as for inflammatory dermatoses such as localized scleroderma, acne vulgaris, and leishmaniasis.

Historical Aspects

Principles of Photodynamic Therapy

PHOTOSENSITIZERS The ideal photosensitizer for PDT in dermatology should meet the following criteria: (1) chemical purity, (2) high singlet-oxygen quantum yield, (3) significant light absorption at wavelengths that penetrate the skin sufficiently deeply, (4) high tissue selectivity, and (5) efficacy after topical application.

Porfimer sodium (Photofrin), a mixture of several hematoporphyrin derivative (HpD) ethers and esters, has a low selectivity for skin tumors and leads to long-lasting photosensitivity; consequently, it is far from ideal for dermatologic use. In contrast, 5-aminolevulinic acid (ALA) or its methyl ester (MAL), intermediates in heme biosynthesis, induces the synthesis of photosensitizing protoporphyrin IX in the target tissue.[90] In this case, the concentration of the photosensitizer depends on the metabolic status of the diseased tissue. ALA in combination with the blue light was approved by the U.S. Food and Drug Administration in 1999 for the treatment of actinic keratoses. In Europe, New Zealand, Australia, and South America, MAL has also been registered for actinic keratoses, superficial and nodular BCCs, and Bowen disease.

Most photosensitizers generate singlet oxygen with a quantum yield between 5 percent and 20 percent. A high quantum yield means that less sensitizer is required in the target tissue to induce sufficient PDT effects. The light absorption maxima of the current sensitizers is in the visible range (400 nm to 700 nm). In this range, light penetration in tissue is only up to 3 mm, limiting PDT to superficial tumors unless interstitial light propagation is used. A high selectivity for sensitizer accumulation in target tissue is necessary to avoid damage to surrounding normal tissue, and this is particularly important when larger areas are treated (e.g., actinic keratoses). So far, only ALA or MAL show reasonably high selectivity after topical application. The ratio of porphyrin induction in skin tumors to the surrounding tissue is higher than 10:1,[91] likely due to a combination of enhanced ALA-MAL penetration through an abnormal stratum corneum and altered metabolism and accumulation within the pre-malignant or malignant cells.

LIGHT SOURCES AND DOSIMETRY Light penetration into skin increases with longer wavelengths up to 1100 nm. Although porphyrins absorb maximally in the Soret band (400 to 410 nm, blue light), there are minor absorption peaks at longer visible light wavelengths. To increase depth of penetration while matching the absorption maxima of porphyrin photosensitizers, wavelengths around 630 nm are often used. Lasers are effective but they are quite expensive, require regular maintenance, and have a small treatment aperture. Hence, simpler incoherent light sources represent a valuable alternative. Fluorescent lamps or light-emitting diodes with appropriate red or blue light emission are commercially available and designed for treatment of large surface areas. Also, intense pulsed light sources are used for dermatologic PDT. Dosimetry depends on the photosensitizer and light source used, as well as on the condition to be treated. For PDT of epithelial cancer, photosensitization must be sufficient to induce necrosis or apoptosis. With current incoherent light sources (lamps, light-emitting diodes), the treatment duration, exclusive of ALA-MAL incubation time, is approximately 10 to 15 minutes. For treating inflammatory dermatoses, significantly lower doses suffice because the goal appears not to be cell death but rather sublethal damage or modulation of cellular functions.

MECHANISM OF ACTION PDT-induced effects are mediated by photooxidative reactions. During irradiation, the photosensitizer absorbs light (energy) and is converted to an excited (triplet) state. The energy can then be transferred to molecular oxygen (type II photo-oxidative reaction), resulting in the generation of reactive oxygen species, mainly singlet oxygen. The biologic effects can be divided into primary cellular and secondary vascular damage. With HpD, early visible damage consists of cell membrane defects as a consequence of lipid peroxidation with consequent cell lysis. Depending on the intracellular localization of the photosensitizers, damage to sub-cellular structures, such as mitochondria, lysosomes, or endoplasmic reticulum, also occurs, whereas DNA is not a primary target. These direct effects probably play a key role in topical PDT, whereas vascular effects after systemic administration of photosensitizers appear to be the decisive event. These effects consist of vasoconstriction, blood stasis, and thrombosis of tumor vessels leading to tumor ischemia and subsequent necrosis.[92]

Photodynamic Therapy in Dermatology

Table 239-5 lists applications for PDT described in the literature. In contrast to other organs, the skin can be sensitized by either intravenous, topical, or intralesional routes of administration of the photosensitizer.

SYSTEMIC PHOTODYNAMIC THERAPY PDT after systemic administration of HpD and porfimer sodium has been used for

TABLE 239-5
Potential Indications for Photodynamic Therapy

ONCOLOGIC	NONONCOLOGIC
• Actinic keratosis	• Localized scleroderma
• Bowen disease	• Human papillomavirus–associated dermatoses
• Actinic cheilitis	• Epidermodysplasia verruciformis
• Superficial BCC	• Verrucae vulgaris
• Nevoid BCC syndrome	• Condylomata acuminata
• Keratoacanthoma	• Leishmaniasis
• Superficial SCC	• Acne vulgaris
• Kaposi sarcoma	• Rosacea
• Cutaneous metastases (cutaneous T-cell lymphoma)	• Photochemorejuvenation of sun-damaged skin

BCC = basal cell carcinoma.

both skin cancers and inflammatory dermatoses. Standard therapeutic procedures do not yet exist.

Systemic Photodynamic Therapy for Oncologic Indications. Systemic PDT with porfimer sodium for Bowen disease is very effective,[93] but invasive squamous cell carcinomas respond less well, with recurrence rates of up to 50 percent within 6 months. Systemic PDT for BCCs, first used in 1981,[94] has been reported by Oseroff and co-workers[95] to give initial complete responses in 92.2 percent of 77 patients with sporadic BCC or nevoid BCC syndrome.[95] In these patients, the 5-year recurrence rate was 15 percent.

Benzoporphyrin-derivative monoacid ring A (verteporfin), registered for the ophthalmologic indication of age-related macular degeneration, is also under investigation for PDT of BCC and offers a duration of cutaneous photosensitization of less than 72 hours, significantly shorter than that of porfimer sodium.[96]

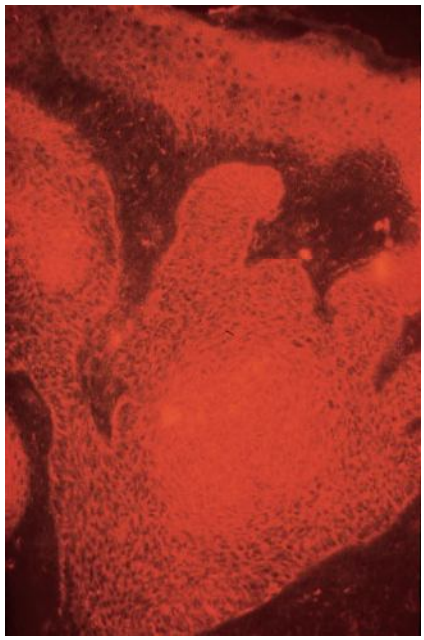
Systemic Photodynamic Therapy for Nononcologic Indications. The use of PDT with HpD was reported for the treatment of psoriasis as early as 1937; better results were reported using red light instead of UVA,[97] and systemic PDT with verteporfin was also investigated in a phase I study of 15 patients in which clinical severity scores for psoriatic plaques improved after five weekly treatments.[98]

TOPICAL PHOTODYNAMIC THERAPY Small hydrophilic molecules like ALA or MAL penetrate well into the skin, particularly if the stratum corneum is abnormal, as is the case in some epidermal tumors.[90] In addition, epidermal cells and the pilosebaceous unit synthesize porphyrins to a much greater extent than fibroblasts, myocytes, or endothelial cells;[91] and epithelial tumors generally synthesize much higher amounts of protoporphyrin IX than the surrounding tissue and can therefore be destroyed without equivalent damage to healthy skin (Fig. 239-7).[90,99] Topical ALA-MAL–induced photosensitivity is thus restricted to the target area. Systemic porphyrin induction is not observed after topical application.[100] The only significant side effect of topical ALA-MAL PDT is a stinging pain during and shortly after irradiation, proportional to the intensity of the phototoxicity reaction.

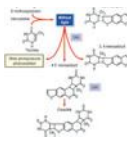
Topical Photodynamic Therapy for Oncologic Indications.[101–108] The experience with treatment of epithelial cancers and pre-cancerous conditions with PDT to date suggests that actinic keratoses,[101–103] Bowen disease (Fig. 239-8),[104] superficial and nodular BCCs,[105–107] and SCCs (tumor thickness less than 2 mm) are suitable for topical ALA/MAL-PDT. For this purpose, ALA is applied topically for variable incubation periods, with or without occlusion, followed by visible light exposure.

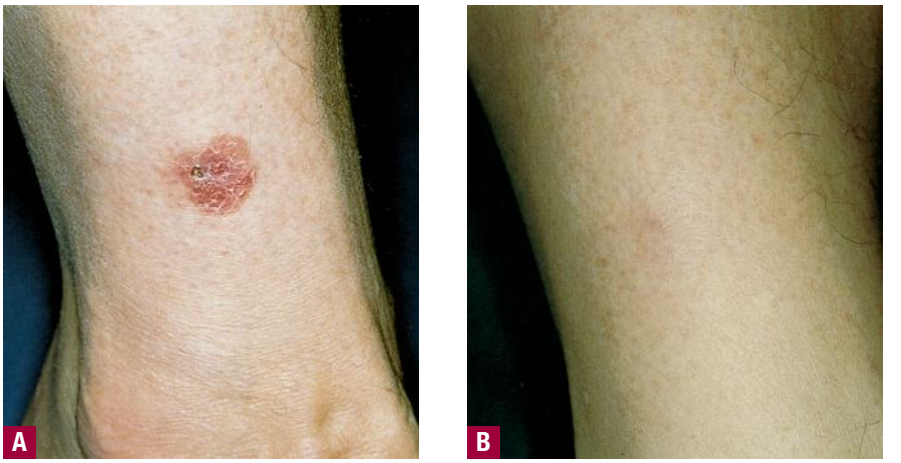
Actinic keratoses, have been studied most extensively and respond to PDT as readily as to local cryotherapy or to broad area 5-fluorouracil (see Chap. 220) or imiquimod therapy (see Chap. 221) administered over weeks to months. Topical application of a 20 percent ALA solution for 14 to 18 hours followed by irradiation with blue light (417 nm) for 1000 seconds (10 J/cm^2) clears more than 80 percent of actinic keratoses after 1 to 6 months,[102] and 90 percent complete clearance at 1 and 5 months was observed after one full face treatment using a 1- to 3-hour incubation period.[102,103] However, cutaneous metastases of malignant melanoma, pigmented BCC, and sclerodermiform variants of BCC respond poorly to ALA-PDT,[108] probably because of insufficient porphyrin synthesis and/or penetration of light within the lesions.[99] Treatment efficacy is enhanced by repeated treatment sessions.[108]

In superficial and nodular BCCs, two randomized phase-III studies have been reported so far comparing MAL-PDT with either surgery or cryotherapy. After an observation period of 60 months, MAL-PDT for superficial BCC showed a similar recurrence rate as cryotherapy (22 percent versus 20 percent). In nodular BCC, MAL-PDT was compared with simple excision; recurrence rates after 60 months were 14 percent and 4 percent, respectively. In both studies, the cosmetic outcome was considered superior for the PDT-treated groups.[108] Indeed, these and other reports[107] suggest that a major theoretic benefit of ALA/MAL-PDT is elimination of skin cancers without scarring, as well as prevention

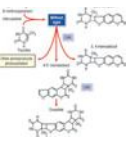


▲ **FIGURE 239-7** Endogenous porphyrin fluorescence after topical application of 20 percent aminolevulinic acid formulation to a solid basal cell carcinoma. Twelve hours after aminolevulinic acid application there was strong fluorescence of the tumor-bearing areas, and weak to no fluorescence of the surrounding dermis. Also visible is fluorescence in the overlying epidermis. (From Szeimies RM, Sassy T, Landthaler M: Penetration potency of topical applied α-aminolevulinic acid for photodynamic therapy of basal cell carcinoma. *Photochem Photobiol* **59**:73, 1994.)





▲ **FIGURE 239-8** Bowen disease. **A.** Lesion located on the right lower leg. **B.** Twelve months after topical aminolevulinic acid-photodynamic therapy [10 percent aminolevulinic acid ointment, application for 4 hours, irradiation with Argon-pumped dye laser (175 mW/cm^2; 180 J/cm^2)], clinically and histologically there were no signs of tumor residue.



of such lesions in high-risk patients treated periodically with broad area PDT.

CTCL (mycosis fungoides) also responded in eight single case reports to ALA-MAL PDT after several treatment sessions. Controlled investigations are currently not available, and, as with PUVA treatment of single lesions, this treatment would not be expected to prevent the appearance of new lesions in other areas.

Topical Photodynamic Therapy for Non-Oncologic Indications.[110–125] Few data are available regarding the treatment of inflammatory and proliferative skin conditions. These include psoriasis, localized scleroderma, human papilloma virus (HPV)–associated conditions, leishmaniasis, acne, and rosacea.

ALA/MAL-PDT is also effective for acne and rosacea, although optimal protocols have not been developed. In two separate studies,[119,120] 22 patients with mild to moderate acne on the back received 20 percent ALA cream under occlusion for 3 hours. The areas were then exposed to broadband (550 to 700 nm) or laser light (635 nm) using various protocols. The authors observed a significant reduction in inflammatory acne lesion counts compared with baseline that persisted at least 20 weeks in some patients.[119] One study found a reduction in sebaceous gland size and sebum secretion, as well as reduced fluorescence attributable to *Propionibacterium acnes*,[119] although the other did not.[120]

PDT with ALA has also demonstrated to enhance the treatment of photodamaged skin with a variety of lasers and light sources. Improvement of global appearance, fine lines, tactile skin roughness, mottled hyperpigmentation, and telangiectasias has been described.[122–126]

Perspectives

The efficacy of PDT in the treatment of superficial neoplastic skin lesion, particularly actinic keratoses, Bowen disease, and superficial BCCs, has been sufficiently documented. PDT may also find a place in the treatment of selected patients with inflammatory dermatoses. Nonetheless, the limitations of both systemic and topical PDT have to be kept in mind. Crucial issues are the depth of the penetration of light, as well as of the sensitizer, into the skin, and inability to assure complete eradication of malignancy by histologic criteria.

CHAPTER 240

Lasers and Flashlamps in Dermatology

Fernanda H. Sakamoto
Tomi Wall
Mathew M. Avram
R. Rox Anderson

Lasers are extremely precise surgical tools and have the qualities of a "magic bullet"—light traverses tissue without effect until it is absorbed by specific targets, where therapeutic chemical, thermal, and/or mechanical excitation occurs. The versatility of lasers and their older cousins, xenon flashlamps, is impressive.

ELECTROMAGNETIC RADIATION, LASERS, AND FLASHLAMPS

Light is a small slice of the electromagnetic radiation spectrum (EMR), of which the quantum is called a *photon*. The wavelength of EMR is inversely proportional to the amount of energy each photon carries. From short-wavelength high-quantum energy to long-wavelength low-quantum energy, EMR includes γ rays, x-rays, ultraviolet (UV) light, visible light, infra-red radiation, microwaves, and radio wave energy. Fundamentally these are all versions of photon energy, traveling at the ultimate speed, the speed of light. Photon absorption is always the inverse of photon creation—the photon is produced when charged matter releases energy and is extinguished (absorbed) when charged matter is promoted to a higher energy state. Thus, the energy of an absorbed photon must correspond to some allowed transition of an electron between atomic orbitals, or the vibrational energy of molecular nuclei. This is why molecules have distinct absorption bands at some wavelengths, whereas the same molecule is transparent at other wavelengths. Light-absorbing molecules are called *chromophores*.

The reciprocal nature of photon absorption and photon creation is in part what makes lasers possible. The word *laser* is an acronym for *l*ight *a*mplification by *s*timulated *e*mission of *r*adiation. Albert Einstein predicted that one photon could stimulate the emission of another photon by interacting with an excited molecule. Inside a laser, this occurs in an excited medium present between two mirrors that pass light back and forth through the laser, so that the light gains in intensity by stimulated emission with each pass. Laser light can be amplified to extreme power levels. Xenon flashlamps are intense light sources that emit a broad spectrum of UV, visible, and infra-red light. Almost every camera has a small xenon flashlamp. When filtered to emit a certain band of wavelengths, flashlamps have some features of the long-pulsed (millisecond) lasers used in dermatology. These filtered flashlamps are often called *intense pulsed light sources (IPLs)*. The brightest IPL is trillions of times dimmer than the brightest laser, however.

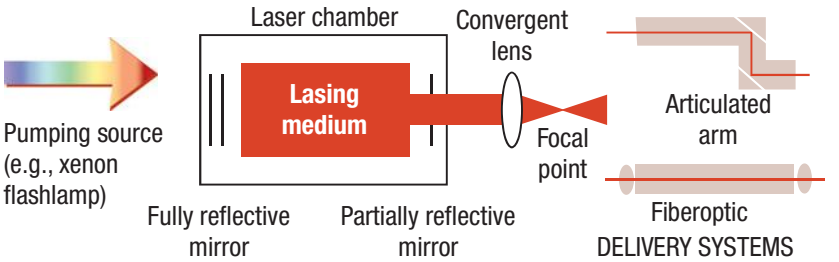
A laser emits an intense, collimated beam of light at a well-defined wavelength, which can be tightly focused, during essentially any period of time. In contrast, an IPL emits broad-wavelength pulses of divergent light that cannot be tightly focused. The most powerful IPLs deliver approximately 1000 W of optical power per square centimeter (10^3 W/cm^2), whereas dermatologic lasers deliver from 10^3 to 10^9 W/cm^2. The record is an astounding approximately 10^{19} W/cm^2, equivalent to packing most of the sunlight striking the earth into 1 cm^2.

Laser emission can be continuous, quasi-continuous, or pulsed (Fig. 240-1). When the emission is focused and scanned, interaction with a given point on the skin may be equivalent to a pulse. Quasi-continuous lasers emit a train of low-energy pulses that usually act in aggregate as a continuous beam. Pulsed lasers in dermatology are high-energy devices that produce either millisecond (10^{-3} second)—or nanosecond (10^{-9} second)—domain pulses. IPLs emit millisecond-domain pulses. A technique called *Q-switching* produces nanosecond laser pulses by suddenly releasing all of the excited-state energy from a laser medium. Ultrashort lasers emit pulses in the femtosecond (10^{-15} second) domain. A femtosecond is very brief—it is to 1 second as 1 second is to approximately 30 million years. Femtosecond lasers are now widely used in biology for two-photon microscopy, which makes possible the equivalent of in vivo fluorescence and immunofluorescence microscopy. Laser light is also coherent, which means that the electromagnetic waves of laser photons are perfectly in phase with each other. Coherence is useful for diagnostic imaging applications.

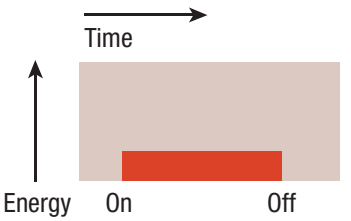
LASERS AND FLASHLAMPS AT A GLANCE

- Lasers are the most precise and selective surgical tools in existence.
- Non-scarring treatment of vascular lesions, pigmented lesions, tattoos, and hair follicles relies on a process called *selective photothermolysis*. For each of the aforementioned broad indications, there are lesion variants that are highly responsive to laser therapy, lesions that are occasionally responsive, and lesions for which laser treatment is contraindicated.
- Pulse duration strongly influences safety and efficacy, and in general should be about equal to the thermal relaxation (cooling) time of specific targets in a given patient.
- Port-wine stains are congenital neurovascular lesions best treated in early childhood that respond well, but rarely completely, to laser treatment.
- Laser treatment is useful for treatment of ulcerated infant hemangiomas.
- Fractional resurfacing is a technique in which thousands of laser microbeams per square centimeter are used to stimulate epidermal and dermal remodeling. It is a less invasive treatment for photoaging than is ablative laser resurfacing.
- Use of any laser or flashlamp (intense pulsed light) for hair removal poses a severe risk of eye injury when used near the eye. Other risks include fires, inhalation of the vaporized tissue plume, electrocution, and a host of side effects such as stimulation of facial hair growth, pigmentary changes, and scarring.

There are four general groups of visible-wavelength lasers used in dermatology (Table 240-1): the group of green and yellow millisecond-domain pulsed lasers used mainly to treat vascular malformations, hemangiomas, scars, photoaging, proliferative lesions, and epidermal pigmented lesions [potassium-titanyl-phosphate (KTP) lasers, pulsed dye lasers (PDLs)]; the group of red and near–infrared millisecond-domain pulsed lasers

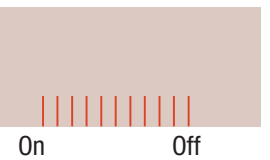


A. Schematic of a typical laser light source. Electrical, chemical, or optical energy input is provided by the pumping source. Note that the initial wavelength of the emitted laser beam is determined by the lasing medium, although this can be altered. Laser energy is delivered to the target via an articulated arm or fiberoptic cable.

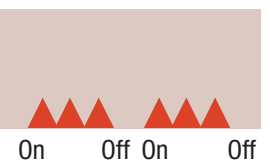


B. Continuous wave (CW) mode profile, (e.g., CO_2, argon lasers)

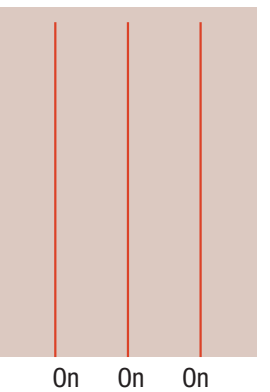
C. Pulsed mode profile (e.g., pulsed dye laser, diode, ruby, alexandrite)



D. Quasi-continous wave (QCW) mode profile (e.g., KTP, copper vapor)



E. "Stuttered" pulse mode profile, as seen in long-pulsed dye lasers and IPLs.



F. Q-switched (QS) mode profile (e.g., QS ruby, Nd: YAG, alexandrite)

▲ **FIGURE 240-1** Schematic diagram of pulsed and continuous lasers. KTP = potassium-titanyl-phosphate; IPL = intense pulsed light (source); Nd:YAG = neodymium:yttrium-aluminum-garnet.

used to treat hypertrichosis and pigmented and deep venous lesions [ruby, alexandrite, neodymium:yttrium-aluminum-garnet (Nd:YAG) lasers]; the group of low-power continuous green or yellow lasers used to treat superficial telangiectasia and perform photocoagulation of lesions; and the group of Q-switched lasers used to remove tattoos and treat dermal melanocytoses, drug hyperpigmentation, and many pigmented lesions. IPL sources also cover much of the visible and near–infra-red spectrum. To some extent, IPLs can mimic some of the output and uses of long-pulse (millisecond-domain) visible lasers, but IPLs are incapable of mimicking high-power infra-red lasers, Q-switched lasers, or focused laser microbeams. Since the advent of selective photothermolysis in the early 1980s,[1] target-selective pulsed lasers and IPLs have largely replaced older continuous-wave devices such as argon-ion lasers.

The near–infra-red region (700 to 1200 nm) is the deepest tissue–penetrating optical radiation. Laser emissions in this spectral region are weakly absorbed by blood and melanin. Near–infra-red lasers include alexandrite devices (approximately 760 nm), diode devices (approximately 800 nm, 940 nm, and others), and Nd:YAG devices (1064 nm). Alexandrite and Nd:YAG laser devices are available in both long-pulse (millisecond) and Q-switched (nanosecond) versions, sometimes in the same machine. Semiconductor diode lasers are very efficient, small, solid state devices that cannot be Q-switched. The most popular laser for hair removal is an 810-nm diode laser array with an integrated skin cooling window. Continuous near–infra-red lasers are also used for endovenous laser therapy of the deep refluxing veins for treatment of varicose disease.

With radiation in the mid–infra-red region (1200 to 2500 nm), there is little or no photon absorption by blood or melanin, and photon absorption is due to vibrational excitation of water, lipids, and proteins. Mid–infra-red lasers are used for non-ablative treatment of photoaging, acne, and various upper dermal lesions. These devices include a semiconductor diode laser near 1450 nm delivered with skin cooling, an Nd:YAG laser at 1320 nm delivered with skin cooling, and an erbium fiber laser near 1550 nm that delivers approximately 1 million microspot laser exposures over the face for fractional resurfacing.[2]

In the far–infra-red region (more than 2500 nm), vibrational excitation of water is very strong. Erbium and CO_2 lasers are used for skin resurfacing by precise vaporization of epidermis and upper dermis to treat photoaging, scarring, and lesions, including warts and benign adnexal tumors. Erbium laser resurfacing is so precise that stratum corneum can be painlessly vaporized as a means for drug delivery. CO_2 lasers (10,600 nm) are workhorse surgical lasers that remove approximately 100 μm (0.1 mm) per pass during resurfacing, with little or no hemorrhage.

SKIN OPTICS (See Chap. 88)

The optical properties of skin are complicated and variable, and change with every heartbeat, every season, and over decades with aging. Two processes determine the optics of skin: scattering and absorption. There are hundreds of chromophores in skin. The dominant ones are as follows: UV spectrum—strong absorption by DNA, protein, and melanin; visible spectrum—absorption by melanin, hemoglobin, oxyhemoglobin, hemosiderin, bilirubin, carotenoids, cytochromes; near–infra-red spectrum—weak absorption by melanin, hemoglobin, oxyhemoglobin, cytochromes; mid–infra-red spectrum—absorption by water, lipids; far–infra-red spectrum—strong absorption by water.

Scattering is a change in the direction of propagation of a photon. Reflection

TABLE 240-1
Common Lasers and Flashlamp Sources in Dermatology

Laser Type	Wavelength (nm)	Mode/Pulse Width Range	Typical Uses	Primary Indication
Excimer	193, 308, 355	QCW (ns pulses)	Treatment of psoriasis and vitiligo, atopic dermatitis phototherapy	Ultraviolet B phototherapy
Argon-ion	488, 514	CW	Coagulation, treatment of telangiectasia	—
Cooper vapor/bromide	512, 578	QCW (ns micropulses)	Treatment of telangiectasia, coagulation	Vascular
KTP	532	QCW, CW, or pulsed	Treatment of vascular lesions (adults more than children) and epidermal pigmentation, coagulation	Vascular
Pulsed dye (yellow)	577–600	Pulsed 0.45–1.5 ms; 10–40 ms stuttered	Treatment of vascular lesions (adults and children, especially PWS), warts, scars, photoaging	Vascular
Long-pulsed ruby	694	Pulsed 3 ms; 100 ms stuttered	Hair removal, treatment of some nevi	Hair removal
QS ruby	694	QS 20 ns	Treatment of epidermal/dermal pigmentation, lentigines, nevus of Ota; removal of tattoos (black, blue, green)	Melanin and tattoos
Long-pulsed alexandrite	755	Pulsed 1.5 ms; 40.0 ms stuttered	Hair removal, treatment of leg veins and hypertrophic PWS	Hair removal
QS alexandrite	755	QS 50–100 μs	Treatment of epidermal/dermal pigmentation, lentigines, nevus of Ota; removal of tattoos (black, blue, green)	Melanin and tattoos
Diode array	810	Pulsed 5–1000 ms	Hair removal, leg veins and venous lakes	Hair removal
Long-pulsed Nd:YAG	1064	Pulsed or stuttered, 3–100 ms	Hair removal in dark skin, treatment of leg veins and venous lakes	Hair removal
QS Nd:YAG	1064	QS 5–10 ns	Treatment of dermal/drug pigmentation and nevus of Ota, removal of tattoos (black)	—
Mid-IR Nd:YAG	1320	Pulsed 20–50 ms stuttered macropulses	Non-ablative dermal remodeling	Non-ablative dermal remodeling
Mid-IR diode	1450	Pulsed 160–260 ms	Non-ablative dermal remodeling, fractional resurfacing	Non-ablative dermal remodeling
Er:glass	1540	Pulsed 1–10 ms	Non-ablative dermal remodeling, fractional resurfacing	Non-ablative dermal remodeling
Er:YAG	2940	Pulsed 0.1–3 ms	Ablation of epidermal lesions, skin resurfacing	Epidermal ablation/laser skin resurfacing
Xenon flashlamp (IPL)	500–1200	Pulsed 2–7 ms; 20–100 ms stuttered or single pulse	Treatment of vascular (telangiectasias) and pigmented lesions, hair removal, non-ablative dermal remodeling	Vascular

CW = continuous wave; Er = erbium; IPL = intense pulsed light; IR = infra-red; KTP = potassium-titanyl-phosphate; Nd = neodymium; pulsed = high-energy pulses; PWS = port-wine stain; QCW = quasi-continuous wave (a rapid low-energy pulse train); QS = Q-switched; YAG = yttrium-aluminum-garnet.

and refraction are special cases of optical scattering. In general, scattering is due to local fluctuations in the refractive index, which is defined as the speed of light in a vacuum divided by the speed of light in the medium. The refractive index of stratum corneum is approximately 1.55, similar to that of a piece of glass. At normal incidence, reflection from the skin surface is approximately 5 percent, enough to cause an eye injury to a laser surgeon who does not wear proper protective eyewear. The surface reflectance carries the visual cues for surface texture (rough, smooth, oily, scaly, etc.). The remaining 95 percent of incident light enters the skin, where photons may be absorbed by chromophores and/or scattered by molecules, particles, fibers, cells, and other structures. In normal epidermis, melanin and cell nuclei account for most of the optical scattering. In dermis, type I collagen fibers account for most of the optical scattering. For radiation across the UV and visible spectrum, one can consider epidermis to be a thin optically absorbing layer dominated by its melanin content, whereas the dermis is a thick optically scattering layer with embedded absorbing structures such as blood vessels and hair follicles. The strength of optical scattering varies inversely with wavelength, so that short wavelengths are more strongly scattered. This accounts for the Tyndall ef-

fect. A light-absorbing substance in the dermis, such as melanin (as in nevus of Ota), carbon (as in a tattoo), or a large cavity (as in dermal cysts), causes blue skin color because the long-wavelength (red) light tends to be lost. Skin has an "optical window" of deeply penetrating light of 620 to 1200 nm. Absorption spectra of the dominant skin chromophores relevant for laser dermatology and effective optical penetration depth are shown in Fig. 240-2.

DOSIMETRY AND LASER-SKIN INTERACTIONS

Light is a form of energy, measured in joules (J). The rate of energy delivery is called *power*, measured in watts (W). One watt is equal to 1 J/s fluence, sometimes called *energy density* or *exposure dose*, refers to the delivered energy per unit area of skin, usually expressed in joules per square centimeter. Irradiance, sometimes called *power density*, is the power delivered per unit area of skin, expressed in watts per square centimeter. For all sources, fluence is the time integral of irradiance; that is, for pulsed lasers fluence is approximately equal to irradiance times pulse duration.

All laser-skin interactions begin with absorption of optical energy. Light can initiate biochemical reactions through photochemistry, can heat tissue to the point of coagulation or vaporization, and can fracture or explode tissue structures by very rapid local heating. The latter occurs only with pulsed high-intensity lasers. Most of the useful dermatologic lasers are based on exploitation of thermal or thermomechanical effects. The important exceptions are the 308-nm excimer lasers used for UV phototherapy, laser activation of photodynamic therapy drugs, and laser diagnostic imaging.

A useful time and temperature "cookbook" can be constructed for laser photothermal events in skin. For example, fibroblasts and most other human cells are killed when exposed to 47°C (116.6°F) for 20 minutes, but can survive 100°C (212°F) boiling water for approximately 10^{-3} seconds. Therefore, selective photothermolysis with pulsed sources often requires local high temperatures in cellular targets such as nevi, blood vessels, and hair follicles. Sublethal thermal injury triggers a complex cascade of events, including heat shock anti-apoptosis gene expression. The thermal behavior of type I collagen in the extracellular matrix plays a major role in laser dermatology. Fibrillar collagen has a well-defined melting point of 60°C to 70°C (140°F to 158°F) depending on degree of cross-linking, and the fiber shrinks dramatically. Skin shrinkage is prominent during CO_2 laser resurfacing, causing some "tightening" of the skin.

Selective Photothermolysis

Light can pass through skin with no effect until it is absorbed, creating heat only at certain targets. Factors affecting where light is absorbed are the location and concentration of skin chromophores, laser wavelength, aiming of the laser beam, and exposure spot size. Light with larger exposure area tends to penetrate more deeply. Selective photothermolysis[1] is a simple concept (with many interesting and still poorly understood nuances) with three basic requirements. First, the target structures must have preferential absorption at a wavelength that reaches to the depth of the structures. Second, the light pulse(s) must be delivered within a sufficiently short time so that the target structures do not transfer much heat to their surroundings during the pulse duration. Third, the fluence delivered by the optical pulse must be great enough to have a therapeutic effect but less than that causing non-specific thermal damage. Targets with excellent absorption contrast include blood vessels, hair follicles, pigmented cells, tattoo ink–laden cells, and, in principle, any structure with sufficient endogenous or exogenous chromophore content. Selective photothermolysis was initially conceived as a means for treating pediatric port-wine stains (PWSs), based on the hypothesis that microscopically selective damage to abnormal venules would lead to microscopically selective repair without scarring. That hypothesis is clearly true, and selective photothermolysis has become routine. However, it should be noted that skin is a particularly robust organ, capable of surviving a nearly complete loss of its microvascular circulation for several days. Similarly, laser-induced removal of the entire epidermis, laser destruction of terminal hair follicles, and selective necrosis of phagocytic dermal cells are usually tolerated without scarring. There are many interesting and clinically important nuances of selective photothermolysis. For example, it is not necessary for the wavelength to be at an absorption maximum of the target chromophore. In fact, there is some advantage to using a wavelength at which light penetration within the targets is equal to or greater than the target diameter, because this ensures even heating throughout the targets. The effective treatment depth can be adjusted by regulating wavelength, fluence, exposure spot size, or compression of the skin.

Choice of pulse duration is critical to clinical success. The thermal relaxation time, τ_r, of any tissue target can be estimated as $\tau_r \approx d^2$, where τ_r is expressed in seconds and d is the target size in millimeters. This simple approximation is useful in clinical practice, because the ideal light pulse duration for selective photothermolysis is about equal to or somewhat less than τ_r for the intended targets.

Photomechanical Interactions

When water inside skin is rapidly vaporized, steam bubbles violently expand and collapse. This process is called *cavitation*. Cavitation is responsible for the petechial hemorrhages seen after PDL and some KTP laser or IPL treatments at pulse durations of less than approximately 1 millisecond. Laser tattoo removal uses photomechanical effects, including cavitation. The rate of target cell heating during Q-switched laser treatment of tattoos and pigmented lesions is an amazing 10 billion °C/second (18 billion °F/second), which causes rupture of the target cells. The desired immediate response to Q-switched laser treatment is whitening (see Fig. 240-6), due to transient gas bubble formation after cavitation.

Vaporization and Skin Resurfacing

Strongly absorbed laser pulses are the most precise surgical tools, vaporizing a very thin layer of tissue per pulse. Through control of the depth of a residual layer of thermal coagulation from zero to several hundred micrometers, hemostasis can also be adjusted. As in selective photothermolysis, pulse duration is adjusted to minimize heat transfer from the superficial layer heated during photon absorption. Temperature in the heated layer is driven to approximately 300°C (572°F), which causes very rapid vaporization of the layer. Most of the energy delivered by the laser pulse goes to the creation of steam, which is removed when the tissue layer flies away. Skin resurfacing is one setting in which "turning down" the laser can in practice cause much greater skin injury due to lack of heat removal.

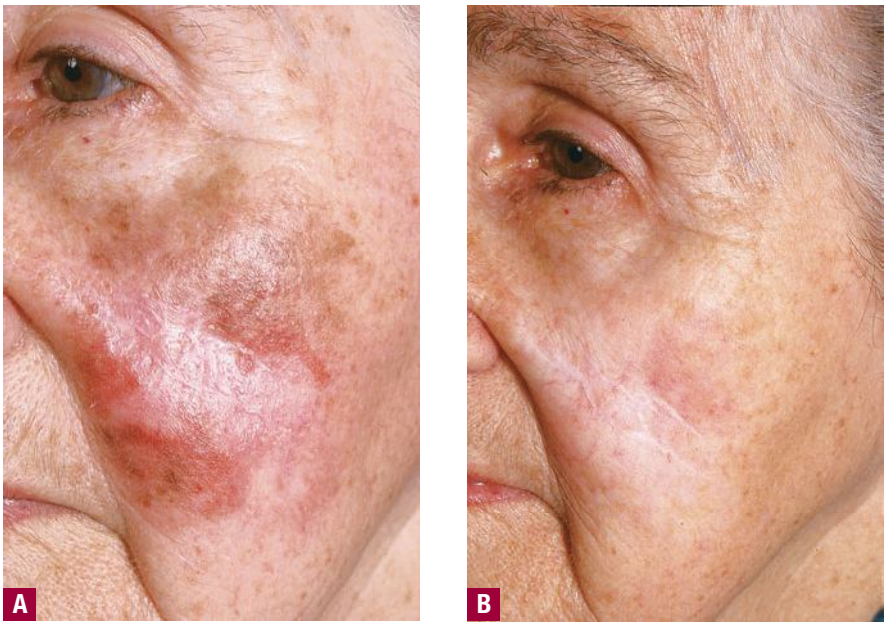
smaller than in cases where smaller individual doses were used.

Disseminated Actinic Keratoses

There is general agreement that small actinic keratoses are best treated by cryotherapy or curettage and electrodesiccation or equivalent methods. The problem arises in extensive and disseminated actinic keratoses as, for example, on the scalp. Here, again, treatment possibilities include topical 5-fluorouracil, imiquimod, or diclofenac cream, but usually RR are higher or appear sooner than after treatment with radiotherapy. Because these lesions are intraepidermal and often in an atrophic epidermis, the ideal treatment is with grenz rays. The treatment consists of six sessions of 4 Gy twice weekly applied on one or several divided fields (see Table 241-4).[14] At the end of the treatment, an erythema or an exudative reaction will occur. If there is marked pruritus, topical glucocorticoid creams may be of help to the patient. One month after the end of treatment, the erythema will have largely disappeared. The patient has to be instructed to continue sun protection. Recurrences may appear years later.

Bowen Disease/Erythroplasia of Queyrat (See Chap. 113)

Bowen disease/erythroplasia of Queyrat is a carcinoma in situ and is treated in a similar fashion to actinic keratosis, but histopathologically, these lesions are thicker. Even in elderly patients, it is possible to apply grenz rays with a $D_{1/2}$ of 1 mm. If the lesions are more infiltrated, soft x-rays with a quality of 20 kV or more are necessary. The dose schedule can be adapted (see Table 241-4). Again, fractions of single doses of 4 Gy up to total dose around 40 Gy may be used. Exudative reactions have to be expected a little earlier in the genitoanal area. Treatment results are excellent.[14]



▲ **FIGURE 241-1** **A.** Extensive lentigo maligna on the left cheek of a 76-year-old woman before and (**B**) 2 years after grenz-ray treatment [10 × 10 Gy (100 Gy), twice per week].

Lentigo Maligna

Lentigo maligna is a pre-invasive lesion (see Chap. 124) and is an excellent indication for radiation treatment. This treatment modality is not well known because it has been considered non-curative. Recent reports show that treatment results are at least as good as surgical procedures[15–17] As mentioned in Radiation Therapy of Malignant Skin Diseases and Tumors, the inclusion of a wide enough margin is not a problem for the radiation therapist; consequently, a large lentigo maligna is an excellent indication for radiotherapy. The classical treatment schedule is named after Miescher, who proposed five to six doses of 20-Gy grenz rays for medium-sized lesions (around 2.5 cm in diameter). For larger lesions, we prefer to apply 10 to 12 doses of 10-Gy Grenz rays (see Table 241-4). The epidermis in the elderly is atrophic, and, with an HVD of 1 mm, even atypical melanocytes in the upper hair follicles can be reached. A drawback is the fact that clinical invasion to deeper tissue levels cannot be reliably assessed, and even with multiple biopsy cannot be totally excluded, and thus, progression of melanoma can occur. Fig. 241-1 shows a grenz-ray treatment result.

Basal Cell Carcinoma, Squamous Cell Carcinoma, Keratoacanthoma

BCCs, SCCs, and keratoacanthomas are a good indication for radiotherapy with

▲ **FIGURE 241-2** **A.** Basal cell carcinoma on the left inner canthus of a 64-year-old man before and (**B**) 6 months after soft x-ray treatment (40 kV) [12 × 4 Gy (48 Gy), twice per week].

◀ **FIGURE 241-3 A.** Mycosis fungoides in a 42-year-old woman before and (**B**) 1 month after soft x-ray treatment (40 kV) [6 × 2 Gy (12 Gy), three times per week].

soft x-rays or superficial x-rays, provided they are less than 20 mm thick. Some treatment centers use the same treatment schedules for BCCs and SCCs, although one could imagine that SCC should be treated with a higher total dose because it represents a more aggressive tumor.[1] Elderly patients prefer not to come every day for the treatment sessions. Therefore, medium-sized lesions can be treated with a 4-Gy single dose in three fractions per week. There is the possibility of applying a higher single dose, for example 6 to 8 Gy per fraction once or twice a week, to small lesions that cannot be excised. Lesions greater than 5 cm are best treated with daily fractions of 2 or 3 Gy (see Table 241-4). Fig. 241-2 shows the results of treating a BCC as described.

Histopathologic examination of BCC and SCC before initiating treatment is a prerequisite. A large study has shown that sclerosing (sclerodermiform or scirrhous) BCCs or poorly differentiated SCCs have a substantial recurrence rate.[14] Consequently, the sclerodermiform BCC is not well suited for treatment with soft x-rays. These lesions are best treated by Mohs surgery or, if that option is not available, megavoltage therapy.

For keratoacanthomas, the same dose schedule is used as for SCCs.[18] Carcinomas of the skin appendages and carcinomas penetrating into cartilage or bone, localized in the mucous membranes, or arising in chronic scars, are not an indication for soft x-ray therapy.

Cutaneous Lymphomas

In general, T-cell or B-cell cutaneous lymphomas are very radiosensitive.[12,21] With the exception of certain circumscribed B-cell lymphomas or localized CD30$^+$ lymphomas where radiotherapy is curative, radiation treatment for lymphomas is palliative. Total doses in the range of 20 to 30 Gy are commonly used and offer excellent palliation. Doses in this range may result in a relapse rate of up to 30 percent. Single doses of 2 Gy, either daily or three times per week, seem to offer the best local control. See also Table 241-3.

Because of the possible need for the subsequent treatment in adjacent areas, it is important to document the treated areas with photographs, accurate drawings, and, if feasible, tattooing of the corners of the fields with India ink. In most patients, the lesions will not clear during or at the completion of irradiation, and it may take up to 6 to 8 weeks for complete response (Fig. 241-3). For individual skin lesions, energies may range from orthovoltage to electron beam. The depth of infiltration defines the energy of the beam required. Larger, bulkier lesions, such as deep ulcers or lymph nodes, may be treated by either Cobalt or 4 to 6 MeV photons (see Table 241-1).

Kaposi Sarcoma

NON–ACQUIRED IMMUNODEFICIENCY SYNDROME-ASSOCIATED KAPOSI SARCOMA Local irradiation of KS includes the lesion plus a normal tissue border of approximately 1 to 2 cm. Thin, cutaneous lesions can be effectively treated either by superficial x-ray therapy (e.g., 20 to 150 kV) or relatively low-energy electron beams (e.g., 4 to 6 MeV). Thick nodules are best treated by electron beams that encompass the entire lesion homogeneously but spare underlying normal tissues. Lesions on the eyelids are treated most easily by superficial x-rays with protective shields over the eyeball.[14,19]

Based on the available evidence, both local therapy and elective regional therapy are effective techniques for the treatment of classical KS. The literature supports the use of a wide range of doses and fractionation patterns (see Table 241-4). As long as a sufficient dose is delivered (e.g., 20 to 30 Gy in 10 fractions or, for small lesions, 8 Gy in 1 fraction), a salutary outcome is likely.[20]

ACQUIRED IMMUNODEFICIENCY SYNDROME–ASSOCIATED KAPOSI SARCOMA Usually, the same dose schedules are used and no difference is evident, although it may take 3 to 4 months for the tumor to resolve. Radiation-induced edema of the feet or face, as well as symptomatic mucositis, are more severe in patients with AIDS than in other patients.[20]

Radiation therapy may be reserved for specific indications such as pain, ulceration, bleeding, functional impairment (e.g., on the legs), or improvement of the appearance of cosmetically disfiguring lesions (e.g., the eyelids). In the case of palliative radiation therapy for AIDS-associated KS, sufficient dose should be delivered to accomplish the desired goal and maintain that state for as long as possible. The treatment should be delivered as rapidly as possible.

SECTION 39

COMPLEMENTARY AND ALTERNATIVE DERMATOLOGY

CHAPTER 242

Complementary and Alternative Medicine in Dermatology

Alan Dattner

Complementary and alternative medicine (CAM) in dermatology encompasses a wide variety of methods of diagnosis and treatment that both supplement and substitute for conventional dermatologic practice. It is also referred to as *holistic dermatology* in that it addresses the entirety of the individual, including the physical, mental, emotional, and spiritual, as appropriate. The discipline includes integrative dermatology in which alternative systems of diagnosis and healing are combined with conventional practice. These systems may include ancient traditional Chinese medicine, Ayurvedic medicine, American folk medicine, homeopathy, or more recent techniques from chiropractic, energetic medicine, functional medicine, and psychosomatic methods. Furthermore, it includes any other technique that works or makes sense based on science or observation. Increasingly, patients are using CAM methods in addition to their conventional treatment as cosmeceutical and nutraceutical manufacturers offer these products, and CAM practitioners and dermatologists respond to the demand and expectation of patients.

HERBAL MEDICINE

Eclectic practice and off-label use of drugs has always been a part of dermatology, perhaps more so than of medicine in general. These practices provide an approach to deal with disorders of uncertain etiology by incorporating methods from other spheres or from observed benefit. Many of the commonly used medications in medicine derive from herbal medicine.[1] The American "herbal" tradition dates to the Eclectics, a school of physicians who, during the 19th and early 20th century codified the use of Western herbs according to specific indications.[2] Today, many herbs are used, and the methods of selecting specific herb combinations also derives from other traditions.[3] For example, psoralens have been used in China and India for repigmentation of the skin for 4000 years.[4] Other herbs used in treating the skin include mayapple (podophyllin) for condyloma, horse chestnut for leg veins, bloodroot (sanguinaria) for skin tumors, and oatmeal (avena sativa) to soothe the skin.[1]

In addition to specific herbal remedies, some of the philosophic aspects of herbal medicine have been key concepts in dermatology. For example, the principle of using a crude preparation,[5] as opposed to a purified single ingredient as it tends to be used in a pharmaceutic product, was part of Sulzberger's observation regarding the use of tar.[6] It was the crude tar product from the distillery and not a purified derivative that had activity in treating psoriasis. In fact, variation in batch efficacy was assumed to be an indication of the heterogeneous nature of the preparation.

APPROACH TO DISEASE

The hallmark of CAM is a search for the elements in the causal chain of functional disturbances that lead to a skin disorder. For inflammatory disorders, an attempt is made to identify exposures which could stimulate and/or disturb immune responses with secondary targeting of skin structures. The focus of CAM is correcting probable underlying causes, often with treatments that are not scientifically proven in the traditional placebo-controlled, double-blind fashion. The patient assumes the responsibility to make necessary lifestyle changes and the risk of protocols that are not conventional.

COMPLEMENTARY AND ALTERNATIVE MEDICINE AT A GLANCE

- Complementary medicine is a holistic approach to diagnosis and treatment.
- Many dermatologic therapies developed in ways similar to the complementary approach and were subsequently scientifically validated.
- Attention to the environment and its impact on the patient is a fundamental principle of complementary dermatology.
- Herbal therapeutics and diet are two of the primary interventions used in holistic dermatology.

ENVIRONMENT IN COMPLEMENTARY ALTERNATIVE MEDICINE

Cross-Reaction and Molecular Mimicry

In the CAM approach to dermatology, the environment is considered to play a fundamental diagnostic and therapeutic role. Cross-reactions with foods, chemicals,[7] and infectious agents[8] may be a

Copyright © 2008 by The McGraw-Hill Companies, Inc. Click here for terms of use.

key to causing inflammation which itself may play a role in a range of dermatologic conditions. A mainstay of the CAM approach is to search for the inciting cause of an inflammatory response as well as correcting the ongoing memory response using natural means. Eliminating foods which exacerbate eczema, or enhancing food breakdown into smaller, less antigenic fragments by supplementing with digestive enzymes, is an example of how to remove molecular mimics that stimulate skin inflammation.[9]

There is individual specificity in antigen recognition,[10] exposure history, and the type of tissue response to the resulting inflammatory cascade. It is therefore critical to look for the precipitating stimuli of disease onset or aggravation on an individual basis. This concept is accepted for contact dermatitis but not for eczema or psoriasis. At the same time, it is critical to consider the existence of factors that either neutralize or exacerbate the response to those stimuli. A detailed history is paramount to understand why a patient reacts at certain times and not others.

Hepatic Factors

Drug levels may be affected by foods or drugs influencing specific P_{450} enzymes.[11] Chemicals targeted by the liver for removal are first chemically converted by P_{450} isoenzymes to make them either more soluble or more chemically reactive for coupling to molecules in phase II for transport out via renal excretion. With insufficient transporters, these hyperreactive metabolites of the drug, made more chemically reactive by the phase I liver P_{450} enzymes, may combine with molecules on skin tissue structures to create neoantigens. Phase II transport molecules include glutathione, glucuronides, and amino acids.

Dietary Approaches

Oral ingestion is one of the largest sources of foreign material entering the body. It has been established that large molecules, including horseradish peroxidase with a molecular weight over 1,000,000 d can be absorbed intact from the gut.[12] Drugs are well known causes of skin eruptions.[13] Foods have a variety of effects on skin disorders beyond a role as allergens.[14] They can serve as informational molecules to incite eruption, direct or indirect hormonal aggravators, gut permeability modifiers, or influence the ecology of the gut flora. Certain nutrients can overcome the liver's capacity to biotransform harmful antigens and toxic intermediates or aid in hepatic biotransformation. Foods can also have a wide variety of effects partially overlapping those of herbs and pharmaceuticals. Dietary effects on gene expression and individual specific food interaction is now known as *neutragenomics*.[15]

Dietary treatment of acne was much more prevalent before the advent of antibiotics. Only recently milk has been again demonstrated in the literature to play an etiologic role in this disorder.[16]

"FOOD ALLERGY" DETERMINATION AND ELIMINATION In addition to classic immunoglobulin E–mediated allergic response, the term *food allergy* also includes other types of allergy such as immune complex, delayed, and Toll-like receptor activation. There is also non-allergic sensitivity. Food allergies develop to the most common foods such as wheat, milk, soy, yeast, and corn. Some believe that a hallmark of food allergy is food craving with repetitive eating of the same food each day.[17] A 5-day elimination and re-challenge on the sixth day is an effective way to determine if the food under consideration is the cause of the symptoms of concern. Other symptoms beyond the skin could include digestive upset, nasal stuffiness, fatigue after eating, or even "brain fog." *Brain fog* is a popular term for a sense of mental confusion, sluggishness, and slowness which may sometimes include a feeling of unreality or disorientation. Small peptides from casein digestion known as *caseomorphins*, which can also derive from gluten, rice, bovine albumin, and even spinach, have psychoactive properties.[18] Treatment involves elimination, substitution with other foods, and food rotation. Enhancing digestion with digestive enzymes and adding metabolites to enhance gut permeability barrier (leaky gut) helps further in prevention of sensitization to disease inducing cross-reactive antigens.[19,20]

GUT FLORA Abnormal gut flora, including overgrowth of *Candida* sp., parasites, and pathogens can lead to inflammation, which compromises the gut barrier and can lead to "leaky gut." Numerous studies from Scandinavia show the importance of probiotic supplementation for reducing by half the incidence of atopy in infants.[21,22]

ESSENTIAL FATTY ACIDS Essential fatty acids (EFAs) play an essential role in skin health. EFAs are the precursors of the eicosanoids produced when phospholipase cleaves a lipid fragment, arachidonate, from the cell membrane. Arachidonate, a common pathway byproduct from most foods, leads, via cyclooxygenase, to production of the pro-inflammatory prostaglandin E_2 (PGE_2), or via lipoxygenase to production of pro-inflammatory leukotrienes.[23] Specific ω-6 unsaturated EFAs such as γ-linolenic acid, found in borage oil, evening primrose oil, and human breast milk, lead to formation of the anti-inflammatory PGE_1. ω-3 unsaturated fatty acids such as those found in fish oils contain eicosopeneinoic acid (EPA), which leads to formation of the anti-inflammatory and anti-clotting PGE_2. Flaxseed oil has an ω-3 EFA known as *α-linolenic acid,* which requires two carbon chain elongation to become EPA. ω-3 EFAs also play a role in formation of the barrier lipid in the stratum corneum barrier. Partially hydrogenated oils not only lead to pro-inflammatory PGE_2 formation, but they inhibit the δ-6-desaturase which is crucial for formation of anti-inflammatory γ-linolenic acid.

Shifting the balance toward anti-inflammatory EFAs by removing foods with pro-inflammatory oils and increasing foods and supplements with anti-inflammatory oils (i.e., cod liver oil) is a strategy useful in most conditions involving inflammation and dry skin. It is especially useful in seborrhea and eczema. Rare problems with excessive fish oil include increased bleeding tendency[24] and high-birth-weight, post-mature babies.[25]

COMPLEMENTARY AND ALTERNATIVE MEDICINE APPROACHES TO SPECIFIC DERMATOLOGIC CONDITIONS

Several dermatologic disorders, primarily inflammatory in nature, may benefit from the CAM approach.

Seborrheic Dermatitis (See Chap. 22)

Seborrheic dermatitis[27] involves inflammation in sebaceous follicular areas of the scalp, eyebrows, and nasolabial folds. All of these regions harbor the yeast *Malassezia*, which is normal follicular flora. There is evidence that *Malassezia* is cross-reactive with *Candida albicans*,[28] and it is postulated here that a cross-reactive attack against antigenic epitopes on the *Candida* and other yeasts and molds becomes directed against the *Malassezia* organisms in the follicle, causing the inflammation that

incites the erythema and desquamative changes characteristic of seborrhea.

An altered pattern of EFAs in infantile seborrheic dermatitis implicates impaired function of the δ-6-desaturase.[29] Some of the B vitamins previously reported to be helpful in seborrhea may function as co-factors for the this enzyme.[30–32] The tendency toward inflammation is exacerbated by a predominance of arachidonic acid precursors in the cell membranes derived from dietary sources. Treatment by substituting EPA-rich fish oil in the diet and removing partially hydrogenated and saturated oils can reduce this inflammatory state by favoring the generation of anti-inflammatory PGE_3.[33–35] Flaxseed oil is another ω-3 fatty acid and PGE_3 precursor, but the active ω-3 EFA in it, α-linolenic acid, requires chain elongation to be converted to EPA, and this process is not uniform among individuals.[36]

Atopic Dermatitis (See Chap. 14)

Atopic dermatitis is an inflammatory disorder of the skin linked to asthma and hay fever. Dermatologists in the past observed cases in which food was considered a trigger, but were generally puzzled that there did not seem to be a specific food that caused the eczema. One challenge was that eczema could be aggravated by one food, and then after diet change, would be exacerbated by the newly substituted food.

One theory articulated by practitioners of CAM relates to what is known as *leaky gut.*[37] Disruption of the gut barrier can result from inflammation of the intestinal lining. This inflammation may be due to parasites, *Candida* overgrowth, food sensitivity, or to pathogenic micro-organisms. In addition, nonsteroidal anti-inflammatory medications are irritating to the gut lining, as are alcohol and aspirin. Any food introduced repeatedly into such an environment can lead to sensitization to that food. In these cases, it is believed that the uncontrolled atopic becomes sensitive to whatever he/she eats repeatedly to avoid that which caused trouble initially. The milk-allergic infant switched to soy protein soon becomes "allergic" to soy. Inflammation in the gut wall stimulated by soy causes allergy to whatever nutrient is next exposed to the gut immune system. This "vicious cycle" could account for the name *atopic*, which was used to describe the changeable nature of the factors initiating the dermatitis.

Treatment consists of removing abnormal microbes and restoring normal flora, removing irritants, eliminating exacerbating foods, enhancing enzymatic breakdown of foods (digestion), coating the gut with mucilaginous herbs, and providing nutrients to support an intact gut barrier.

Proper colonization of the gut with *Lactobacillus acidophilus* and similar strains has a protective effect against atopy.[38] A corollary of this observation is that repeated use of antibiotics favors overgrowth of *Candida*, and simple starches and sugars support *Candida* growth. It is presumed that consumption of large amounts of yeast, mold, and their byproducts, such as bread, beer, wine, and cheese, could both induce high-dose antigen tolerance to intestinal *Candida*, and perhaps even sensitize to other antigenic determinants. High-dose tolerance is a lack of immunoreactivity to specific antigenic determinants or substances due to the presence of large quantities of these determinants in the system. Treatment consists of removing the dietary factors that favor *Candida* and then treating with herbal or other remedies to reduce the yeast population. Artemisia annua and short-chain fatty acids such as undecylenic or caprylic acid are a few such treatments. Next, probiotics can be added to prevent *Candida* from overgrowing.

Only when these steps have been taken should pharmaceuticals be used in a progressive fashion. Otherwise, one risks selecting for resistant strains. Nystatin may be considered, followed by ketoconazole and fluconazole. Nystatin should be slowly increased in dosage from 500,000 units/day in divided doses to 6 million units, over 10 to 12 days. Highly yeast-sensitive individuals absorb cell content material through an already leaky gut wall and are known to develop exacerbation of previous symptoms and sometimes fever, with a Herxheimer-like reaction. All of these drugs have more potential effectiveness when the environment is changed by dietary restrictions on sugars, simple carbohydrates, and foods high in or derived from yeast.

Anti-inflammatory EFAs, such as EPA from fish oils and γ-linolenic acid from borage or evening primrose oil, appear to help some atopics,[39] but this effect is disputed by some meta-analyses.[40]

Acne (See Chap. 78)

Before the availability of tetracycline, diet change was a mainstay in acne treatment. With the advent of antibiotics for acne, many dermatologists argued that the stress from restricting favorite foods was itself acne causing, and consensus evolved to minimize the role of diet in acne. This view was supported by seminal papers that demonstrate that common agents such as chocolate do not cause acne.[41] More recent data do show a relationship between total skim and regular milk and acne.[42] The authors postulate hormones and bioactive molecules as a possible reason for this effect. Milk protein allergy causing an inflammatory response that blocks the infundibular apparatus could also contribute.[42] It now appears that diet may influence a number of mechanisms related to acne development.[43]

Bovine milk production by postpartum cows results in milk that contains placenta-derived progesterone and dihydrotestosterone precursors. Other hormones in addition to steroids in milk may also stimulate acne. The most frequently implicated substance is IGF-1 (insulin-like growth factor), which also increases during the teenage years. IGF-1 is present in organic milk and increased in milk from cows treated with bovine growth hormone. IGF-1 increases lipogenesis in sebocytes.[44] It has also been shown that excess carbohydrates increase insulin, which increases IGF-1, which in turn worsens acne.[45] IGF-1 and dihydrotestosterone levels in women both correlate with acne.[46]

Milk elimination and reduction in carbohydrate ingestion can cause a substantial improvement in some acne patients, as does reduction of pro-inflammatory fats from fried and partially hydrogenated sources. In women with peri-menstrual flaring, reduction of dietary estrogens and pseudoestrogens may be helpful. Herbs that balance hormones and enhance elimination of stimulatory antigens and pseudoestrogens from the environment may help as well.

SECTION 40

SURGERY IN DERMATOLOGY

CHAPTER 243

Dermatologic Surgery: Introduction to Anatomy and Approach

Sumaira Z. Aasi
Brent Pennington

Dermatologic surgery has rapidly become a cornerstone of the practice of dermatology. Factors such as the epidemic of skin cancer, the interest in maintaining a youthful appearance for an aging population that is living longer, and the financial pressures to perform surgery in less expensive outpatient settings have led to an increase in the number of surgical procedures performed in dermatologic practice.

ANATOMY

Anatomy is often called the language of surgery.[1,2] Knowledge of anatomy is critical for a number of reasons, including communicating precisely with colleagues, performing efficient and safe procedures, obtaining optimal functional and aesthetic reconstruction, understanding the lymphatic drainage, and anticipating the metastatic spread of malignancies. As the majority of cosmetic and surgical procedures are performed on the face and because of its complexity, this chapter focuses on the superficial cutaneous anatomy of this critical region.

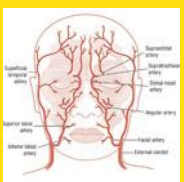
Cosmetic Units and Landmarks

Landmarks and cosmetic units help to localize areas of the face accurately and precisely for purposes of communication with colleagues and to perform the surgery itself. For instance, it is more helpful to describe a lesion on the face if it is said to be located on the "left nasal sidewall" versus left nose or "right triangular fossa" versus right ear. Cosmetic units are zones of tissue that share cutaneous features such as color, texture, pilosebaceous quality, pore size, and degree of actinic exposure. These cosmetic units are demarcated by junction lines that can be discrete (eyebrows) or subtle (nasofacial sulcus). Cosmetic units can also be further divided into subunits. Because of the tissue similarity, it is often best to reconstruct a surgical defect within a cosmetic unit or subunit or borrow tissue from nearby units. In addition, scar lines can be hidden easily in junction lines between the cosmetic units. The more complex regions of the face that have multiple subunits include the nose, ears, and lips (Figs. 243-1 and 243-2).

The subunits of the nose include the glabella (the area between the eyebrows), the root (the deep sulcus below the glabella and uppermost portion of the nose), dorsum or bridge (the area overlying the nasal bone), lateral sidewalls (the sides of the nose), nasal tip, the nasal ala (the nostril), alar groove and nasolabial crease (the grooves that demarcate the alae superiorly at the lateral nasal sidewall and inferiorly at the lip, respectively, and the columella (the mobile linear structure separating the alae inferiorly) (see Fig. 243-1).

The lateral surface of the ear is rimmed by the helix, a curved cartilaginous structure that begins at the crus just above the external auditory canal and continues around the ear to end at the fleshy lobule. The central concavity within which the external auditory meatus lies is the concha. The concha is divided by the crus of the helix into a superior portion, the cymba, and an inferior portion, the cavum. The posterior border of the concha is formed by another cartilaginous structure called the *antihelix*. Superiorly, the antihelix originates from two legs (*crus* is Latin for *leg*): the supe-

INTRODUCTION TO DERMATOLOGIC SURGERY AT A GLANCE



- Profound knowledge of the anatomy, particularly of the head and neck region, is essential.
- Preoperative assessment includes a thorough medical, drug, and medication history.
- Asepsis and antisepsis are required.
- The choice of the anesthetic is determined by the nature and duration of the procedure and by patient factors such as allergy or renal or hepatic impairment.
- Side effects of local anesthetics are pain, a vasovagal reaction, or (uncommon) allergic reactions. Anesthetic toxicity is rare.
- Infiltrative anesthesia, nerve blocks, and topical anesthesia (for minor procedures) can be performed.
- Types of suture material and suturing technique depend on the surgical procedure.
- Postoperative care is essential.

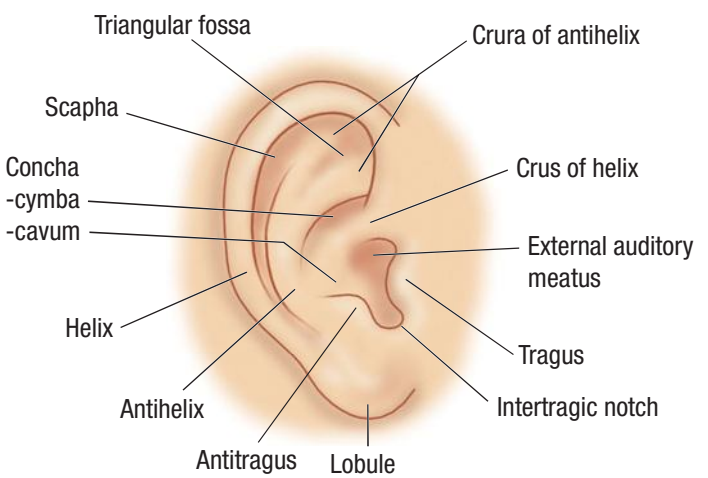
▲ **FIGURE 243-1** Cosmetic units and landmarks of the face.

rior crus and inferior crus. The region between the crura is referred to as the triangular fossa. The groove between the helix and antihelix is the scaphoid fossa. The triangulated cartilaginous structure just anterior to the auditory canal is called the *tragus,* and just posterior to this is the triangulated end of the antihelix, referred to as the *antitragus*. The inferior region between the tragus and antitragus is the intertragic notch (see Fig. 243-2).

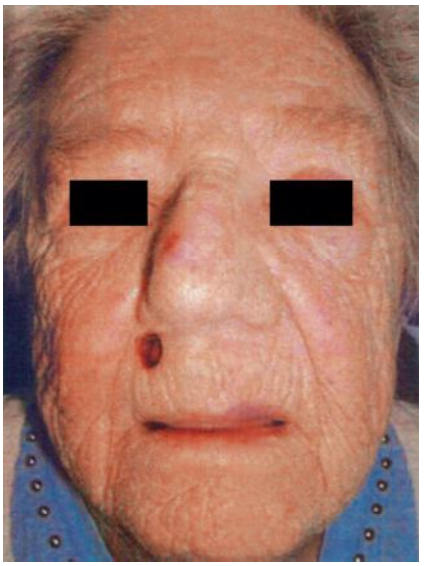
The upper lip has a concave depression in the center, called the *philtrum*, which is bounded by two ridges, the philtral crests. There is a prominent crease, the mental crease, which divides the cutaneous lower lip from the chin. The boundary between the red mucosal surface of the lips and the cutaneous surface is called the vermillion border. The raised contoured area of the inferior portion of the philtrum is a critical aesthetic landmark known as the *Cupid's bow* (see Fig. 243-1).

Relaxed Skin Tension Lines

Relaxed skin tension lines (RSTLs) are another characteristic of the face that help guide surgical reconstruction and allow the structural camouflage of scar lines. RSTLs are creases on the face that



▲ **FIGURE 243-2** Landmarks of the external ear.



▲ **FIGURE 243-3** Relaxed skin tension lines of the face.

form over time due to factors such as loss of elastic tissue tone, lengthening of the collagenous fibrous septae that connect the dermis to the underlying facial muscles, development of excessive skin, gravity, and ultraviolet radiation exposure. Fig. 243-3 illustrates a surgical defect on the upper lip of an elderly woman with prominent RSTL. RSTLs are most obvious on the face because unlike other muscles in the body that connect tendons and bones, facial muscles attach to the overlying skin. These lines can be induced by facial muscle movement in the young but inevitably become more pronounced with age. RSTLs usually run perpendicular to the underlying muscles. In most situations, the long axis of the excision should be placed parallel to the RSTL because they are often in the direction of the least tension for a scar. It is preferable to design flaps such that the majority of the scar lines fall within the RSTL.

Danger Zones

There are three main danger zones that are critical to understand while performing surgical procedures on the head and neck. Each of these zones involves a motor nerve and the muscles it innervates. It is important to confirm the proper function of these muscles before performing a procedure in these areas so that it can be readily determined whether an injury occurred during surgery.

TEMPORAL BRANCH OF THE FACIAL NERVE

The temporal branch of the facial nerve is at greatest risk for injury where it

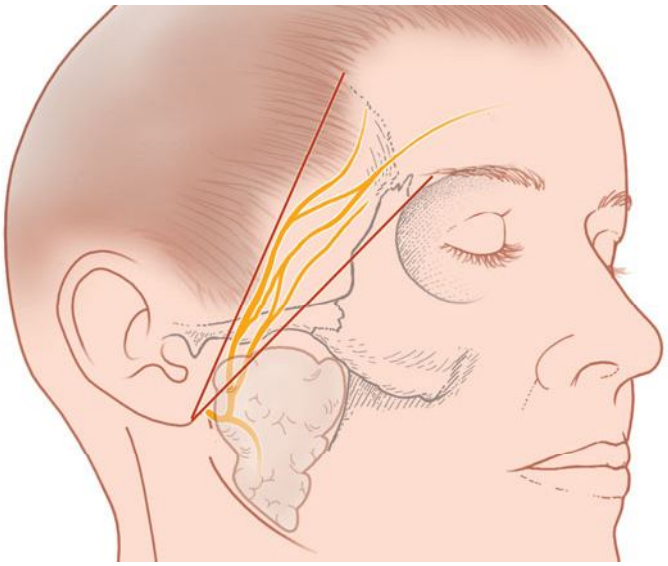
crosses the zygomatic arch. Injury to the temporal branch of the facial nerve leads to an inability to elevate the eyebrows and brow ptosis and paralysis. Asymmetric appearance of the forehead can also occur because there will be a loss of the lines and wrinkles on the affected side. One easy method to delineate the danger area of the temporal nerve is to draw a line from the earlobe to the lateral edge of the eyebrow, and the tragus to just above and behind the highest forehead crease (Fig. 243-4). In the area between these lines, the nerve is superficial, and it is critical to undermine just below the dermis in the superficial fat above the fascia.

MARGINAL MANDIBULAR NERVE Damage to the marginal mandibular nerve allows contralateral and upward pull on the mouth while the ipsilateral mouth is fixed in a grimace with a lip drop. As it crosses the angle of the mandible at the inferoanterior border of the masseter, the marginal mandibular nerve is covered only by skin, subcutaneous fat, and fascia, which may be thin in this location, particularly in the elderly.

SPINAL ACCESSORY NERVE Injury to the spinal accessory nerve leads to the paralysis of the trapezius with winging of the scapula, shoulder drop, inability to shrug the shoulder, difficulty with abducting the arm and chronic shoulder pain. Transection of the spinal accessory nerve can occur when operating in the posterior triangle of the neck. This region is delineated by the clavicle inferiorly, the sternocleidomastoid muscle anteriorly, and the trapezius muscle laterally and posteriorly. One can anticipate the location of the spinal accessory nerve by drawing a line connecting the angle of the mandible with the mastoid process. Where a vertical line drawn dropped 6 cm from the midpoint of this line meets the posterior border of the sternocleidomastoid muscle is Erb's point. The spinal accessory nerve emerges approximately from this point and lies superficially here, covered only by skin and fascia.

Undermining Planes

SUPERFICIAL MUSCULOAPONEUROTIC SYSTEM The term *fascia* refers to connective tissue that contains both fibrous and fat tissue in various amounts. Superficial fascia is the subcutaneous tissue that is immediately below the dermis. The deep fascia consists of more compact and highly organized collagen fibers. The superficial musculoaponeurotic system (SMAS) is the fascial system that envelops the muscles of the face. It stretches over the cheeks between the temporalis and frontalis muscles above and the platysma muscle below. The SMAS also attaches to the orbicularis oculi muscles anteriorly, the trapezius muscle posteriorly, and includes the fascia of the forehead and galea of the scalp. Most of the superficial muscles of the scalp and face insert into the skin either directly through fibrous bands running in the subcutaneous tissue or indirectly by attachment to the SMAS, which, in turn, is attached to the skin. In the lateral areas of the face, the SMAS is organized and more visible but becomes less discrete medially. Because of its attachment to the skin superficially and muscles deep, the SMAS coordinates a wide range of facial expressions. In addition, the SMAS is an important landmark because most major arteries and nerves run within or deep to it. Thus, dissection above the SMAS allows one to safely avoid injuring branches of the facial nerve (see Chap. 194).



▲ **FIGURE 243-4** Danger zone for the temporal nerve.

SCALP The scalp is classically divided into five layers that are often referred to by the mnemonic SCALP. These layers from superficial to deep are: *s*kin, sub*c*utaneous tissue, *a*poneurosis (galea aponeurotica), *l*oose connective tissue, and *p*eriosteum. Because the majority of the nerves and vessels of the scalp are superficial to the subgaleal space, this is an ideal undermining plane. However, it is also known as the *danger zone* because hematomas and infection can develop here and pass through the emissary veins into the meninges.

FOREHEAD The forehead is best undermined immediately above the superficial fascia of the frontalis muscle. There may be little subcutaneous fat in this area. The temple should be undermined in the high fat/subdermal region to avoid damaging the temporal branch of the facial nerve.

EYELIDS The eyelids possess the thinnest skin of the body. The skin of the eyelids lies directly on the orbicularis muscle. Undermining should be performed above the muscle fascia to avoid causing significant bleeding and scars/contractures that can lead to ectropion.

CHIN AND LIPS The large, thick muscles of the lips and chin can make undermining challenging. The chin, in particular, has muscles broadly attached directly to the skin. Sharp undermining performed just above the superficial muscular fascia is appropriate. These areas are at high risk for bleeding, made even more precarious by functions such as talking and chewing.

NOSE The nose requires different levels of undermining in different regions. The dorsal nose can be easily undermined above the periosteum, especially when performing reconstruction with flaps. The distal, more sebaceous portion of the nose must be undermined in the sub–fibro-fatty layer to allow the greatest tissue movement.

CHEEKS The cheeks can be safely mobilized in the high or mid subcutaneous fat. Care must be taken when undermining in the hair-bearing regions of the

cheek in men, however. Here, undermining should be performed in the deep subcutis to avoid transecting hair follicles.

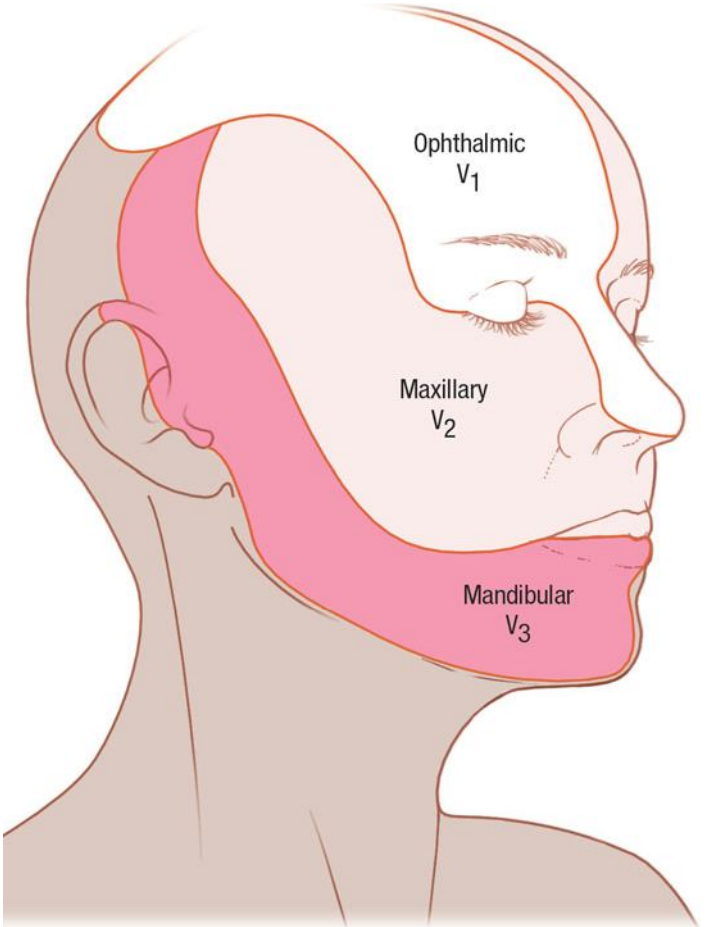
NECK The neck can be safely undermined while staying above the superficial fascia. One must be careful in the posterior triangle of the neck. This region is delineated by the clavicle inferiorly, the sternocleidomastoid muscle anteriorly, and the trapezius muscle laterally and posteriorly. The spinal accessory nerve lies superficially here, covered only by skin and fascia.

Sensory Nerves

The trigeminal nerve (cranial nerve V) provides the majority of the sensory innervation of the face (Fig. 243-5). It exits the skull via three foramina located bilaterally in the mid-pupillary line, the supraorbital, infraorbital, and mental foramina. The first branch, the ophthalmic nerve (V_1), has several branches that supply the innervation to the superior portion of the face: the supraorbital, supratrochlear, infratrochlear, external nasal, and lacrimal nerves. The supraorbital (lateral) and supratrochlear (medial) nerves supply the forehead and anterior scalp and are branches of the frontal nerve (the largest branch of the ophthalmic nerve). They exit from two notches along the orbital rim: supraorbital foramen or notch laterally, and supratrochlear notch, medially. The infratrochlear branch (of the nasociliary nerve) supplies the glabella, nasal root and bridge. The external nasal branch (or the dorsal nasal nerve) is a branch of the anterior ethmoidal nerve of the nasociliary branch of V_1. The external nasal branch supplies the dorsal nose and provides the anatomical explanation of Hutchinson sign that can occur in some cases of herpes zoster of the ophthalmic nerve. Vesicles on the nasal tip indicate that the eye may be involved because the nasociliary branch of V_1 sends branches both to the nasal tip and the cornea. The lacrimal branch supplies sensation to the upper eyelid.

The second branch of the trigeminal nerve is the maxillary nerve (V_2). The maxillary nerve supplies sensation to the lateral nose, lower eyelid, superior cheek, and anterior temple. The maxillary nerve gives off two main branches that supply the skin of the face. The zygomatic branch of the maxillary nerve gives rise to the zygomaticofacial nerve, which exits the skull through the lateral zygomatic bone and supplies a small area of the lateral canthus. In addition, the zygomatic branch also gives rise to the zygomaticotemporal nerve, which exits the skull through the anterior temporal fossa and supplies skin of the anterior temporal region. The largest branch of the maxillary nerve is the infraorbital nerve that exits the skull through the infraorbital foramen of the maxilla. This supplies sensation to the eyelid and superior cheek.

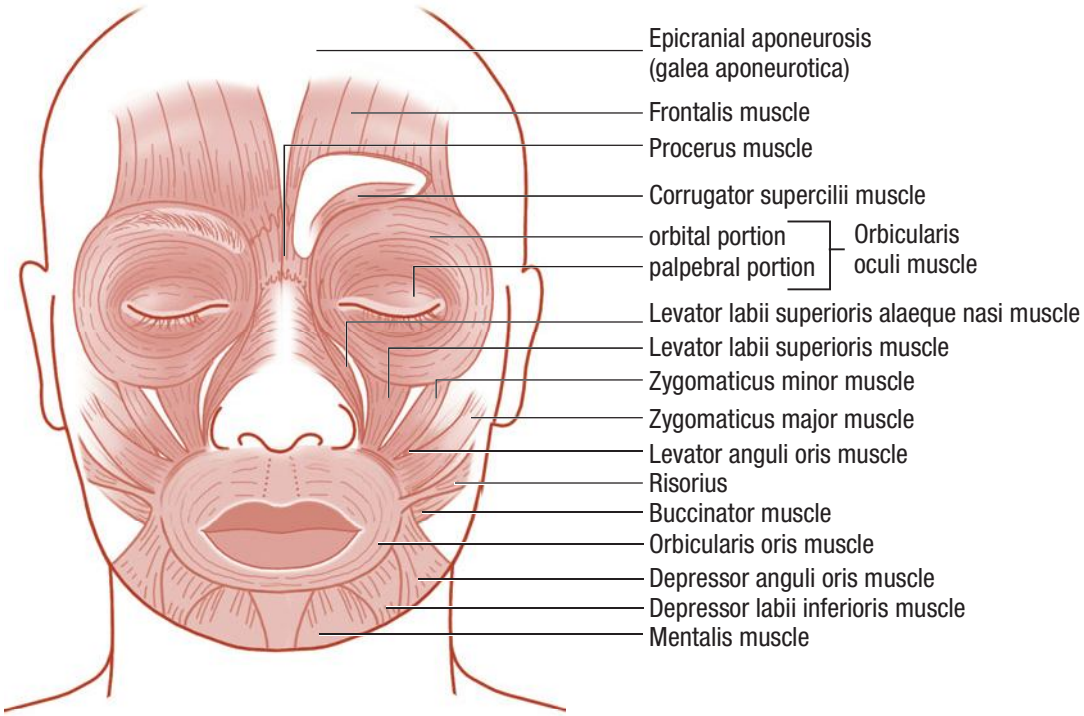
The third branch of the trigeminal nerve is the mandibular nerve (V_3). Its branches provide sensory innervation of the lower lip, chin, mandibular and preauricular cheek, anterior ear, and the central temporal scalp. The mandibular nerve gives off three major cutaneous branches: the auriculotemporal, buccal, and mental nerves. The auriculotemporal nerve innervates most of the temple, the temporoparietal scalp, the anterior ears, parts of the external ear canal, and the tympanic membrane. The buccal nerve lies deep to the parotid gland and supplies the skin over the buccinators, buccal mucosa, and the gingiva. The mental nerve exits through the mental foramen and is a continuation of the inferior alveolar nerve. The mental nerve supplies sensation to the lower lip and chin.



▲ **FIGURE 243-5** Sensory distribution of the trigeminal nerve.

Muscles

The scalp has two muscles overlying it, the frontalis anteriorly and the occipitalis posteriorly. These muscles are joined by a thick fascia centrally over the scalp, the galea aponeurotica. The frontalis muscle also covers the forehead and elevates the eyebrows. The eyebrows move medially and downward with contraction of the corrugator supercilii muscles. The procerus lies between the supercilii muscles and draws the skin of the forehead inferiorly to create the horizontal creases at the root of the nose. The orbicularis oculi muscle surrounds the eye and consists of an orbital and palpebral portion. The orbicularis oculi muscle serves to close the eyes with the palpebral part with both reflexive and voluntary control and the orbital part with voluntary control. The central sphincter-like muscle around the mouth is the orbicularis oris. This muscle helps to purse the lips to form certain sounds and whistle. The lip depres-



▲ **FIGURE 243-6** Muscles of facial expression.

sors are: depressor anguli oris, depressor labii inferioris, and the mentalis. The lip elevators are: the zygomaticus major, zygomatic minor, levator anguli oris, levator labii superioris and the levator superioris alaeque nasi. The risorius helps to retract the corner of the mouth. The buccinators and masseter muscles help with mastication (Fig. 243-6).

Motor Nerves

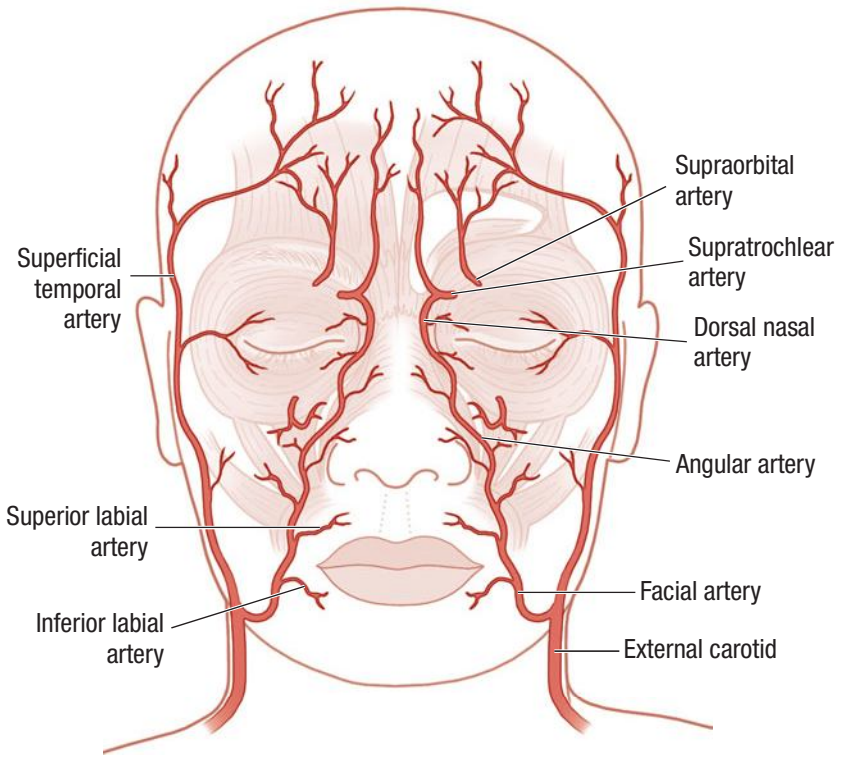
The facial nerve (cranial nerve VII) provides innervation to all the muscles of facial expression. It exits the skull via the stylomastoid foramen which lies deep in the infraauricular sulcus and anterior to the mastoid process. The facial nerve enters the parotid gland at the level of the intertragic notch and usually divides into five branches within the substance of the gland. The well-known mnemonic "To Zanzibar By Motor Car" can be used to remember the five main branches: *t*emporal, *z*ygomatic, *b*uccal, *m*andibular, and *c*ervical. For the most part, these nerves enter the muscles they innervate posteriorly and deep. A nice rule of thumb is that if one transects a nerve lateral to the pupillary line, permanent paralysis can result and if the nerve is cut medial to this demarcation, most nerves will regenerate or have arborizations that will help provide additional innervation.

The temporal branch of the facial nerve exits the superior part of the parotid gland and crosses the zygomatic arch to innervate the frontalis, upper portion of the orbicularis oculi, and corrugator supercilii. Injury to the temporal branch leads to an inability to raise the eyebrows and brow ptosis. The zygomatic branch innervates the orbicularis oculi, nasal muscles, lip elevators, and the buccinators. Damage to the zygomatic nerve results in lower eyelid ptosis and an inability to close the eyes completely. The buccal branch also innervates the buccinators and lip elevators, as well as the orbicularis oris and risorius. Damage to the buccal branch leads to an inability to whistle. The marginal mandibular branch crosses the angle of the mandible at the inferior-anterior border of the masseter. It innervates the depressors of the mouth.

Vascular Supply

The blood supply of the face is almost entirely derived from branches of the external carotid artery (Fig. 243-7). Just posterior and medial to the angle of the mandible, the facial artery branches off the external carotid artery. The facial artery continues anteriorly and superiorly toward the angle of the mouth, giving off the inferior labial artery and superior labial arteries that supply the lips. The continuation of the facial artery in the nasofacial sulcus is called the *angular artery*. The angular artery continues superiorly to enter the orbit immediately over the medial canthal tendon where it anastomoses with the ophthalmic artery, a branch of the internal carotid artery. After giving off the facial artery, the external carotid artery then passes deep to the sternocleidomastoid muscle and enters the body of the parotid gland where it gives off the posterior auricular artery that supplies the postauricular scalp, the maxillary artery, and the superficial temporal artery. The terminal branch of the maxillary artery exits the infraorbital foramen with the infraorbital nerve as the infraorbital artery to supply the lower eyelids and infraorbital cheek.

The terminal branches of the internal carotid artery are the ophthalmic artery branches, the supraorbital artery, and the supratrochlear artery. The supraorbital artery emerges from the supraorbital foramen, whereas the supratrochlear artery emerges more medially. The internal and external carotid systems join in two places: where the supratrochlear branch and the dorsal nasal artery anastomose with the angular artery and where the forehead branches of the supraorbital and supratrochlear arteries anastomose with branches of the superficial temporal artery.



▲ **FIGURE 243-7** Vascular supply of the face.

The veins of the face parallel and lie posterior to the arteries. Unlike the veins of the trunk and extremities, facial veins have no valves. This allows blood to flow in either direction. Thus, in the central face where there are anastomoses between branches of the ophthalmic vein and of the angular vein, infection has easy access to travel along the ophthalmic vein to the cavernous sinus. The angular vein also communicates with the deep facial vein and pterygoid plexus.

Lymphatics

The lymphatic vessels of the face generally drain from superficial to deep and medial to lateral and caudad. While the general drainage patterns are described here, variations can occur. The posterior scalp drains to the postauricular and occipital nodes. The lateral and superior face, the forehead, and the lateral eyelids drain to the parotid nodes. The medial and inferior face, including the medial eyelids and lateral lips, drain to the submandibular nodes. The middle two-thirds of the lower lip and the chin drain to the submental nodes. These nodes can be optimally palpated by performing a bimanual exam with a gloved hand feeling through the floor of the mouth.

The lymph nodes of the head and neck eventually drain into a terminal series of nodes (deep cervical nodes) and finally into the lateral internal jugular chain.

PREOPERATIVE ASSESSMENT

Preoperative assessment is critical for a successful procedure. It can minimize complications and anticipate or possibly correct factors that predispose to adverse outcomes. A fairly thorough medical, drug, and medication allergy history provides an accurate picture of the patient's health status. Questioning the possibility of pregnancy in women of childbearing age should not be overlooked, as local anesthetics and antibiotics may be contraindicated. Patients with inherited bleeding disorders can also be identified and, when possible, given clotting factors to correct for these disorders. Uncontrolled hypertension may predispose to increased intraoperative and postoperative bleeding. In addition, poorly controlled diabetes and immunosuppression with use of systemic steroids for medical conditions, such as autoimmune disorders or organ transplantation, may affect healing time. Information from the social history can also have a bearing on the surgery. For instance, healing can be adversely affected if the patient smokes, and this may impact the decision to perform a flap or graft. Alcohol consumption can increase the risk of bleeding because of its qualitative effect on platelets. Finally, knowledge of the patient's resources and support at home is helpful when providing instructions for postoperative care.

Antibiotics

A well-planned and executed surgical procedure can be significantly compromised by an infection. Infections can lead to poor cosmesis, inconvenience, added expense, and patient dissatisfaction. Because every surgical procedure violates the epidermal barrier, no surgical procedure is absolutely sterile. Hence, all surgical wounds are contaminated by bacteria because of the inevitable resident flora in humans. However, not all contaminated wounds become infected. Infection depends on a large number of factors: the pathogenicity of the microbe, the quantity of the microbe, the length of surgery/timing of infection, the presence of foreign material (sutures, devitalized tissue), presence of dead space, poor suturing/surgical technique, poorly designed reconstruction, compromised vascular supply, and the host and wound's resistance to infection. Usually a wound that contains greater than 10^5 bacteria per gram of tissue is considered infected.[4] The American College of Surgeons has defined wounds as: clean (nontraumatic, without break in aseptic technique), clean-contaminated (minor break in aseptic technique, wounds in oral cavity, axillae, perineum), contaminated (acutely inflamed, major break in aseptic technique) and dirty (encountering pus, fecal, or urinary discharge). Antibiotics can be considered for some clean-contaminated, contaminated, and dirty wounds. Most wounds in dermatologic surgery are clean-contaminated wounds and do not require antibiotics. The most common organism is *Staphylococcus aureus* and a first generation cephalosporin (or clindamycin for the penicillin-allergic) is appropriate when necessary. Studies show that to prevent or change the course of infection, antibiotics must be given within 2 to 3 hours after inoculation and that antibiotics give maximal suppression against infection if given before bacteria colonize tissue. In addition, there is concern that, with increasing time, the wound is sealed off with blood clots and fibrous exudates, and the antibiotic is unable to reach the wound effectively. Routine use of antibiotics postoperatively is discour-

aged because of the risk for resistant bacteria.

Medications

The use of blood thinners, such as warfarin, dipyridamole, clopidogrel, and aspirin, are common in the aging population. In the past, patients were often told to discontinue their blood thinners before surgery. However, recent reports show that discontinuing these medications prior to dermatologic surgery can lead to episodes of thrombotic events such as stroke and pulmonary embolism.[5] Furthermore, remaining on such medications does not lead to significant adverse events. Many patients may be taking herbal or over-the-counter drugs that also interfere with clotting. These are not often considered "drugs" by patients, and thus they may not volunteer taking such supplements unless they are specifically asked. Some common preparations in this category include vitamin E, garlic, gingko, ginseng, feverfew, or ginger. Alcohol can also interfere with platelet aggregation, and it is important to instruct patients to avoid drinking a few days before and after the surgery. Most dermatologic surgeons advise patients to avoid alcohol, herbal products, and nutritional supplements several days before surgery. In addition, patients who are taking aspirin and other nonsteroidal anti-inflammatory drugs for non-physician recommended "preventive" reasons are also advised to discontinue these drugs.

Non-selective β blockers (i.e., propanolol) can occasionally potentiate the effect of epinephrine and lead to complications such as malignant hypertension and bradycardia.

Other preoperative considerations include latex allergy or allergy to topical antibiotics or adhesives in tapes. Use of systemic steroids can prolong the wound healing time.

Pacemakers and Defibrillators

Electrosurgery is widely used in dermatologic surgery to obtain hemostasis. However, electrosurgery can disrupt the function of pacemakers and implantable cardioverter-defibrillators (ICDs) by oversensing, inhibiting firing, device reprogramming, battery depletion, or direct damage to the device.[6] Thus, it is important to identify patients with such devices and to use proper precautions. Fortunately, newer pacemakers and ICDs have improved shielding and are more resistant to the electromagnetic interference that can be produced by electrosurgery. ICDs are more sensitive to electromagnetic interference, and this interference can cause the defibrillator to discharge, leading to significant morbidity and possible mortality for the patient. If electrosurgery is necessary, recommendations, such as using short bursts of electricity (less than 5 seconds) and avoiding its use directly around the area of the pacemaker, may minimize risks. In addition, bipolar electrosurgery creates little interference and is safer. Heat cautery does not cause any interference and is the safest but is not as effective for hemostasis with larger or complicated procedures.

Smoking

Smoking should also be discussed preoperatively with patients. Tobacco use creates vasoconstriction, which impairs wound healing and jeopardizes the reconstruction, especially with more complicated procedures such as flaps and grafts. Patients should be strongly encouraged to cease tobacco use at least 1 week before surgery and 1 week postoperatively. It is also important to clarify that a nicotine patch is not ideal, and patients must avoid nicotine exposure through patches or gum.

Surgical History

A discussion of healing after previous procedures can be informative for the patient and surgeon. The physician can determine if the patient is predisposed to forming hypertrophic scars or keloids and plan reconstruction and postoperative care appropriately. The patient may have a misunderstanding of wound healing and feel that a well-healed visible scar on a high-tension area is a keloid. This can be an opportunity to anticipate patient expectations and educate them on the process of wound healing.

SURGICAL TECHNIQUE

Skin Preparation and Aseptic Technique

The normal skin is colonized by a host of bacteria, primarily aerobic cocci. *S. aureus* is the most common cause of cutaneous wound infections in dermatologic surgery. Other bacteria commonly identified on the skin include *S. epidermidis, Pseudomonas, Propionibacterium,* streptococci, and micrococci. *Pseudomonas* is frequently the pathogen identified in infections of cartilaginous regions such as the ear. The aim of aseptic solutions is to significantly reduce the amount of normal bacterial flora, as complete sterilization of the skin is not possible due to the presence of bacteria in pilosebaceous units. The ideal antiseptic would be nonirritating, non-toxic, nonsensitizing, be effective against all resident and transient microbes, and long-lasting. In prepping the field, shaving the hair creates multiple superficial microabrasions in which bacteria may reside and is associated with an increased incidence of local wound infections. Hair removal, if needed, has the lowest risk of associated infection if done by clipping or depilatory agents.

Iodophors that act through oxidation of cell membranes by free iodine are common topical antiseptics. The most common form of this antiseptic is Povidine-iodine. This antiseptic has broad antimicrobial activity against both Gram-positive and Gram-negative bacteria, as well as fungi, viruses, and mycobacteria. Iodophors have bactericidal activity that persists for several hours after application. On contact with blood or serum, the bactericidal activity is lost, but some bacteriostatic activity is retained. This class offers relatively rapid onset of action within minutes. Side effects of Povidine-iodine include allergic contact dermatitis, irritant contact dermatitis, and possible tissue necrosis with prolonged exposure to large amounts in open wounds.

Chlorhexidine also functions through disruption of cell membranes. It has broad antimicrobial activity with excellent Gram-positive coverage and very good Gram-negative activity. It has some degree of activity against viruses but little effect on mycobacteria or fungi. It offers a more rapid onset of action than Povidine-iodine, providing almost immediate bactericidal activity upon application, which persists for many hours after application. The primary side effects of chlorhexidine are the potential for ototoxicity and keratitis. As a result, it should not be used around the eyes or ears. Similar to iodophors, prolonged exposure of chlorhexidine in open wounds has been reported to be toxic to the tissue.

Isopropyl alcohol and ethyl alcohol are effective antiseptics for minor skin procedures. They function through the denaturation of microbial proteins. They display good activity against Gram-positive bacteria, Gram-negative bacteria, mycobacteria, viruses, and fungi. Alcohols

TABLE 243-1
Local Anesthetics

Generic Name	Trade Name	Primary Use	Relative Potency	Onset	Duration[a] Plain	Maximum[b] Dose Plain (mg)	Maximum[b] Dose with Epinephrine (mg)
Amides							
Bupivacaine	Marcaine	Infiltration	8	2–10 min	3–10 h	175	250
Dibucaine	Nupercaine	Topical	—	Rapid	Short	—	—
Etidocaine	Duranest	Infiltration	6	3–5 min	3–10 h	300	400
Lidocaine	Xylocaine	Infiltration/topical	2	Rapid	1–2 h	300	500 (3850 dilute)
Mepivacaine	Carbocaine	Infiltration	2	3–20 min	2–3 h	300	400
Prilocaine	Citanest	Infiltration	2	Rapid	2–4 h	400	600
Prilocaine/lidocaine	EMLA	Topical	—	30–120 min	Short	—	—
Esters							
Benzocaine	Anbesol, etc.	Topical	—	Rapid	Short	—	—
Chloroprocaine	Nesacaine	Infiltration	1	Rapid	0.5–2.0 h	600	—
Cocaine		Topical	—	2–10 min	1–3 h	200	—
Procaine	Novocaine	Infiltration	1	Slow	1.0–1.5 h	500	600
Proparacaine	Ophthaine	Topical	—	Rapid	Short	—	—
Tetracaine	Pontocaine	Infiltration	8	Slow	2–3 h	20	—
Tetracaine	Cetacaine	Topical	—	Rapid	Short	—	—

[a]In clinical practice the duration of anesthesia appears to be less than stated above, especially for head and neck areas, and addition of epinephrine prolongs anesthesia by a factor of two.
[b]Maximum doses are for a 70-kg person.

have a rapid onset of activity at the site of application, but there is no persistence of this activity over time. The antimicrobial activity of alcohols is not as extensive as that of chlorhexidine or iodophors. In addition, the flammable nature of alcohols limits their use in procedure requiring electrocautery.

Hexachlorophene is rarely used as a skin antiseptic solution. It has excellent Gram-positive activity but limited activity against Gram-negative organisms or fungi. It is also readily absorbed through the skin and has the potential for neurotoxicity, especially in infants.

Local Anesthesia

Effective anesthesia is critical to the successful performance of dermatologic surgery. The overwhelming majority of cutaneous surgical procedures can be performed with local anesthesia. Local anesthesia provides the benefits of rapid onset of action, ease of use, decreased cost, and minimal associated morbidity and mortality.

Nerves transmit stimuli by opening of sodium channels that results in an influx of sodium ions into the nerve cell. This influx results in depolarization of the axon generating an action potential. Local anesthetics exert their effect on nerves by blocking the sodium channels on nerve axons. This blockage inhibits depolarization and the formation of an action potential. Local anesthetics affect the smaller unmyelinated C-type nerve fibers, which carry the sensation of pain and heat, more rapidly and effectively than myelinated A-type nerve fibers, which transmit. Thus, adequate anesthesia can be achieved while motor function and pressure sensation are maintained.

Local anesthetics structurally are composed of three subunits: a hydrophobic aromatic ring, a hydrophilic amine group, and an intervening group connecting the hydrophobic and hydrophilic units. The hydrophobic aromatic ring is responsible for the molecule's ability to diffuse through axonal membranes. The hydrophilic amine maintains the solubility of the compound in aqueous solution and accounts for blockage of the sodium channels of nerve axons. The region connecting the hydrophilic and hyphobic regions may be either an amide group or an ester group. Amide anesthetics, which include lidocaine, prilocaine, bupivacaine and mepivacaine, are metabolized in the liver through dealkylation and hydrolysis by microsomal enzymes. Ester anesthetics, which include procaine, benzocaine, tetracaine, and cocaine, are metabolized by plasma pseudocholinesterase and are excreted renally.

Selecting the Appropriate Anesthetic

The nature of the procedure determines which local anesthetic is ideal (Table 243-1). The primary variables to consider in choosing between anesthetics are the onset of action and the duration of anesthesia. Patient factors to consider in this selection are a history of allergy to an anesthetic class or renal or hepatic impairment. For simple biopsies and excisions, a rapid-onset anesthetic, like lidocaine, with medium duration of action provides effective anesthesia. For more extensive procedures, an anesthetic with a longer duration of action, such as bupivacaine, may be desired. Some practitioners choose to mix a rapid-onset anesthetic with one of long duration into one injectable solution.

Epinephrine

Local anesthetics, with the exception of cocaine, are vasodilators. This vasodilatory effect produces unwanted bleeding at the operative site. Epinephrine with its potent vasoconstrictive effects is often added to local anesthetic preparations to reduce bleeding. Concentrations ranging from 1:100,000 to 1:500,000 are effective in reducing bleeding at the surgical site. In addition to its hemostatic effect, epinephrine reduces the dispersion of the local anesthetic from the operative site. This prolongs the duration and efficacy of the anesthesia by 100 percent to 150 percent. It also limits the potential for systemic toxicity, as less anesthetic is allowed to enter the systemic circulation.

Epinephrine is a potent agonist of α- and β-adrenergic receptors. Absolute contraindications to its use with local anesthetics are pheochromocytoma and

hyperthyroidism. Relative contraindications to the use of epinephrine include severe coronary artery disease, uncontrolled hypertension, peripheral vascular disease, pregnancy, and acute angle glaucoma. In addition, epinephrine should be used with caution in patients on β blockers, monoamine oxidase inhibitors, phenothiazines, and tricyclic antidepressants as these individuals demonstrate greater sensitivity to its effects. Although uncommon, severe hypertension may be encountered in patients on β blockers due to the unopposed α-receptor stimulation of the epinephrine.

The use of epinephrine-containing local anesthetics on anatomic regions with minimal collateral circulation, such as the digits, penis, and nasal tip, is a matter of controversy. Reports of local tissue necrosis in these areas with limited perfusion attributed this result to the potent vasoconstrictive effects of the epinephrine. More recent observations indicate this necrosis to actually be the result of excessive volume of anesthetic used, which physically tamponades the vessels. Thus, local anesthetics with epinephrine are now considered safe for use on the digits, penis, and nasal tip, when used judiciously in small volumes. Consideration may be given to using a lower concentration of epinephrine (1:500,000) for those sites with severely limited perfusion.

Self-limited, systemic side effects may also be experienced with the administration of epinephrine-containing anesthetics. These include anxiety, fear, palpitations, tachycardia, diaphoresis, tremor, and hypertension. Serious side effects of excessive epinephrine administration include arrhythmias, cardiac arrest, and cerebrovascular hemorrhage. These serious side effects are extremely rare when used at appropriate dosages in individuals without significant contraindication.

To maintain the stability of epinephrine in solution, pre-mixed anesthetics are produced in an acidic solution with a pH of between 3 and 5. Injection of this acidic solution into tissue often produces significant discomfort. To avoid this, the pH of the solution can be adjusted before injection closer to the physiologic pH of 7.4 through the addition of sodium bicarbonate. The standard formula for this is the combination of one part of 8.4 percent sodium bicarbonate with 10 parts lidocaine. This buffered solution must be used soon after preparation as the epinephrine gradually degrades at a rate of approximately 25 percent per week. Alternatively, the epinephrine and anesthetic may also be mixed immediately before use, which also provides a neutral solution. In each instance, the neutral or slightly alkaline solution has the added advantages of quicker onset of action and increased anesthetic effect as the pH of the solution is closer to the pKa of the anesthetic, meaning more of the anesthetic is in its active ionized cationic form.

Side Effects

The most common side effect of local anesthetics is the pain of its administration. Pre-mixed local anesthetic preparations containing epinephrine are manufactured as an acidic solution in order to maintain the stability of epinephrine. The addition of sodium bicarbonate to these solutions elevates the pH to a more physiologic level resulting in less discomfort with injection. Slow injection of the anesthetic through a small gauge needle (27 gauge to 30 gauge) also minimizes the pain of injection. Smaller syringes, such as 1 to 3 mL, create less pressure at the site of anesthetic administration. Based on the gate theory of pain perception, repeated pinching or vibration of the immediate surrounding area lessens the perception of the stick at site. Verbal distraction of the patient is also useful in lessening the anxiety and discomfort of the anesthetic.

Injection of anesthetic into the subcutaneous tissue is less painful than injection into dermal tissue; however, a quicker onset of action and longer duration of anesthesia are observed with dermal injection. If a large area is to be anesthetized, the initial injection should be placed near the origination of sensation and proceed distally. Subsequent injections, if necessary, should be made through previously anesthetized tissue. For large areas, consideration should also be given to the use of nerve blocks to minimize discomfort.

One side effect of local anesthetic administration that is not uncommon is the vasovagal reaction. This may be manifested as pallor, weakness, bradycardia, hypotension, diaphoresis, and nausea. Placement of the patient in Trendelenburg position usually results in complete resolution of these symptoms within several minutes. A cool compress on the forehead and fanning the patient are often helpful in comforting the patient during this episode. Patients should be injected in a recumbent or Trendelenburg position to minimize the likelihood of a vasovagal response. These positions also allow providers to be better prepared to deal with the reaction should it occur. Pain and anxiety of anesthetic injection can precipitate a vasovagal reaction; thus, the aforementioned techniques for lessening the discomfort of injection are critical in reducing the likelihood of a vasovagal response.

Allergy to a local anesthetic is an uncommon side effect in dermatologic surgery. True allergic reactions are typically immediate type I immunoglobulin E–mediated reactions, which may produce urticaria, angioedema, bronchospasm, tachycardia, hypotension, and, possibly, cardiovascular collapse. For severe reactions, administration of epinephrine and cardiopulmonary support is indicated. Less commonly, type IV–delayed hypersensitivity reactions may be observed. These present similar to an allergic contact dermatitis in the days following the injection of the anesthetic.

Allergic reactions to ester anesthetics are very uncommon.

For those patients in whom an allergy to an anesthetic is unclear, intradermal prick testing to ester anesthetics, amide anesthetics, sodium metabisulfite, and methylparabens may be helpful. Alternatively, for smaller procedures, diphenhydramine hydrochloride solution provides temporary anesthesia without risk of an allergic response. Antihistamine side effects, including significant drowsiness, may be encountered with its use. Normal saline with preservative may also be used for very brief procedures. The temporary anesthesia it provides is attributed to a combination of the tamponade effect on nerves and the mild anesthetic effect of the preservative benzoyl alcohol.

Anesthetic toxicity is a rare complication given the typical volumes required for dermatologic surgery. Signs of toxicity are usually not observed with dosages less than 5.0 mg/kg of plain lidocaine and 7.0 mg/kg of lidocaine with epinephrine. For tumescent anesthesia, the maximum safe dose increases to 55.0 mg/kg of 0.05 percent to 0.1 percent lidocaine with 1:1,000,000 epinephrine. The initial presenting signs are circumoral numbness and tingling, tinnitus, light-headedness, nausea, and numbness of the distal extremities. With additional anesthetic, more extensive central nervous system depression may occur with hallucinations, seizures, and respiratory depression. Cardiovascular toxicity may also occur, but does so at much higher levels of anesthetic than the initial central nervous system toxicity. The manifestations include hypotension, arrhythmias, and cardiac arrest.

Both central nervous system and cardiovascular toxicity are directly related to serum levels of the anesthetic. Thus, direct intravenous or intra-arterial injection is to be avoided when anesthetizing an area. This can be done by drawing back on the syringe after needle insertion prior to infiltration of the anesthetic to confirm that the needle is not in a vascular structure. The risk of toxicity can be elevated by other medical problems affecting the metabolism of the anesthetic. In particular, patients with liver disease experience increased serum levels of amide anesthetics due to an impaired ability to metabolize and clear the anesthetic. Thus, a lower dosage of an amide anesthetic or a switch to an ester anesthetic is advisable in these patients.

Topical Anesthetics

Several local anesthetics are also available as topical preparations. When used properly, these agents provide suitable anesthesia for minor dermatologic procedures, such as shave biopsies or superficial laser treatments. Their efficacy on normal skin is limited by their ability to penetrate the stratum corneum. Thus, most of the preparations require extended application times and/or occlusion for effectiveness.

LMX is a topical lidocaine cream in a liposomal vehicle. It is available in 4 percent and 5 percent concentrations. EMLA (eutectic mixture of local anesthetics) cream consists of a combination of 2.5 percent lidocaine and 2.5 percent prilocaine. LMX and EMLA have been shown to be more effective than other topical preparations of 4 percent tetracaine gel and Betacaine-LA (a mixture of prilocaine and lidocaine in a liquid paraffin ointment). LMX typically requires an application time of 30 minutes with or without occlusion, whereas EMLA requires 1 hour with occlusion. Multiple studies have demonstrated the 30-minute application of LMX without occlusion to provide equal anesthesia as 1-hour application of EMLA with occlusion. Caution should be exercised in the use of large amounts of prilocaine-containing topical preparations in infants or those with an impaired skin barrier, as prilocaine has the potential to induce methemoglobinemia.

Cryogens, such as ethyl chloride, also provide brief anesthesia at a site for minor procedures or the insertion of a needle. Similarly, an ice cube placed on an injection site often significantly reduces the discomfort of injection in the anxious patient.

Mucosal membranes are readily anesthetized using topical preparations due to the ease of penetration in the absence of a stratum corneum. Tetracaine or proparacaine drops rapidly provide effective anesthesia of the conjunctiva and cornea for insertion of eye shields. Benzocaine and lidocaine preparations provide prompt anesthesia for intra-oral procedures or before nerve blocks.

Nerve Blocks

The use of regional nerve blocks can be of immense value to the dermatologic surgeon. Regional nerve blocks allow large cutaneous areas to be anesthetized with small volumes of anesthetic. They are based on the injection of a local anesthetic into the immediate vicinity of a sensory nerve as it emerges from deeper planes of tissue. This provides effective anesthesia for the patient while minimizing the discomfort of multiple injections. Nerve blocks have the added benefits of limiting the possibility of anesthetic toxicity as well as minimizing tissue distortion. The primary risk of nerve blocks is nerve trauma with resultant neurapraxia.

The standard anesthetic used for regional blocks is 1 percent lidocaine with 1:100,000 epinephrine; however, bupivacaine may be added if more lasting anesthesia is desired. A 1-inch, 30-gauge is suitable for the performance of most nerve blocks. The proper execution of nerve blocks is predicated on a thorough knowledge of the anatomy of the region being anesthetized.

The cutaneous sensation of the face is primarily supplied by the trigeminal nerve, with a small fraction of the periphery being supplied by the cervical plexus. As its name implies, the trigeminal nerve consists of three major divisions: the ophthalmic (V_1), maxillary (V_2), and mandibular (V_3) divisions. Each of these divisions has major branches, which are amenable to regional nerve blocks.

The ophthalmic division gives off the supraorbital, supratrochlear, and infratrochlear nerves. The supraorbital nerve exits through the supraorbital foramen, which is a readily palpable bony notch located along the orbital rim just medial to the mid-pupillary line. The supratrochlear branch exits along the orbital rim approximately 1.5 cm medial to the supraorbital notch. The infratrochlear nerve exits just above the medial canthus. All three of these branches can be anesthetized with a single injection by inserting the needle 2 to 3 mL lateral to the supraorbital notch and advancing medially through the subcutaneous tissue to the medial canthus. The anesthetic is then injected as the needle is slowly withdrawn in one smooth motion. This single injection provides anesthesia to the ipsilateral forehead, frontal scalp, upper eyelid, medial canthus, and superior nasal sidewall and root.

The infraorbital nerve, a branch of the mandibular division, exits through the infraorbital foramen, which is located in the mid-pupillary line approximately 1 cm below the infraorbital rim. This nerve may be blocked by either an intra-oral or a percutaneous approach. The percutaneous method involves insertion of the needle directly over the infraorbital foramen and advancement directly down to the maxillary bone, where the anesthetic is delivered. With the intra-oral approach, the sulcus located just above and lateral to the canine tooth is identified by manual palpation. The needle is inserted in the superior portion of this sulcus and advanced upwards approximately 1 cm in the mid-pupillary line. At this position, the anesthetic is slowly injected. The intra-oral approach is less painful than the percutaneous one, and may be further aided by the use of a topical lidocaine or benzocaine gel on the oral mucosa. This block provides anesthesia to the ipsilateral lower eyelid, medial cheek, upper lip, and upper teeth.

The mental nerve is a branch of the mandibular division, which exits through the foramen just medial to the mid-pupillary line. This nerve is easily accessed via an intra-oral injection. It is located just opposite of the first bicuspid on the mucosa of the lower lip, and is often visible to the naked eye as a thin glistening white strand. It is anesthetized with an injection in the immediate vicinity of its inferior portion. This provides anesthesia to the ipsilateral lower lip and chin.

In addition to the above branches, there are other branches of the trigeminal nerve that are also amenable to regional nerve blocks. These include the buccal, auriculotemporal, anterior ethmoidal (external nasal branches), and zygomaticotemporal nerves. A block of the greater auricular nerve off the cervical plexus provides anesthesia to the posterior auricle and angle of the mandible.

Nerve blocks can be a valuable tool for non-facial locations as well. In particular, digital nerve blocks are very useful for procedures involving the digit or nail

unit. The cutaneous sensation of a digit is supplied by two nerves coursing down each of the lateral aspects of the digit. For a block, the needle is inserted perpendicularly into the lateral aspect of each side of the digit and advanced until bone is reached. At this position, a small volume of anesthetic is administered. The delivery of a large volume (greater than 1 mL) of anesthetic in the digits can result in tamponade of the digital circulation with subsequent necrosis. This tamponade effect now appears to be more critical factor in cases of digital necrosis than the use of epinephrine.

Electrosurgery and Electrocautery (See Chap. 247)

SUTURE MATERIALS The proper selection of suture material for any dermatologic procedure is vital to its successful outcome. There are several intrinsic characteristics of each suture material, which will influence this selection process (Table 243-2). Sutures are produced in both absorbable and nonabsorbable forms. An absorbable suture is classified as one, which loses half of its tensile strength within 2 months. Absorbable sutures are primarily used for the approximation of dermal and subcutaneous tissue. As wounds have achieved less than 10 percent of their final tensile strength at 2 weeks, these sutures maintain the structural support of wounds during the initial healing phase. The time that a suture maintains its tensile strength is dependant on the material of which it is composed.

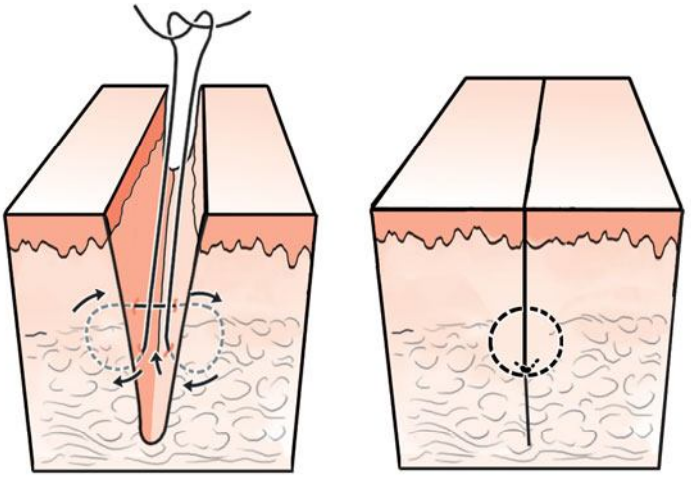
Nonabsorbable sutures are predominantly used for external suturing with subsequent removal in the days after the procedure. In this instance, these sutures are used more for fine epidermal approximation than structural support. On occasion, nonabsorbable sutures are also used for the placement of subcutaneous tissue, muscle, and fascia, when a more permanent placement of the tissue is desired.

Sutures are produced as monofilaments (single-strand) or multifilaments (multiple-braided strands). Monofilaments offer the advantage of increased ease of pull through tissue, less risk of infection, and decreased tissue reactivity. The disadvantage of monofilaments is the increase in memory, or the tendency for a material to revert to its original shape. This memory results in decreased ease of handling of the suture and decreased knots security for monofilaments. Multifilaments, or braided sutures, offer ease of handling and increased knot security. However, the strands of a multifilament have the capability to trap fluid and bacteria resulting in an increased risk of infection with their use.

In general, the smallest suture, which provides adequate tensile strength for a defect, should be utilized. Suture size is measured in multiple of zeros based upon the diameter of the suture material. The higher the number preceding the zero, the smaller the diameter of the suture. Typically, 5-0 and 6-0 sutures are used on regions of low tension, such as the face, eyelids, and ears. Areas of higher tension, such as the trunk, extremities, and scalp, require 3-0 and 4-0 sutures. Areas of intermediate tension, such as the neck, may be closed with either 4-0 or 5-0 sutures. There are a wide range of needles whose nomenclature varies with manufacturer, In general, most skin surgery procedures are best performed with plastic surgery needles.

SUTURING TECHNIQUE Meticulous suturing technique is fundamental to obtaining excellent aesthetic and functional results. Properly placed sutures allow for approximation of wound edges, wound-edge eversion, minimization and redistribution of tension, elimination of dead space, maintenance or restoration of natural anatomic contours, and avoiding permanent suture marks on the skin surface. The suturing technique selected for a specific wound closure depends on the anatomic location, tension, thickness of the wound edges, and goals of the surgeon.

Interrupted Sutures. The simple interrupted suture is the most basic and versatile suture used by dermatologic surgeons. Ab-



▲ **FIGURE 243-8** "Heart-shaped" subcutaneous buried suture.

sorbable, buried interrupted sutures are used as part of the layered wound closure. These sutures provide support for the wound until tensile strength has increased sufficiently to prevent wound dehiscence and reduce tension on the wound edges. To achieve good eversion of the wound edges, these are best placed in the deep dermis and subcutis in a heart-shaped configuration (Fig. 243-8).[7] Wounds in which one skin edge appears higher than the other can be appropriately aligned by taking a larger bite from the lower edge and a smaller, more superficial bite from the higher edge.

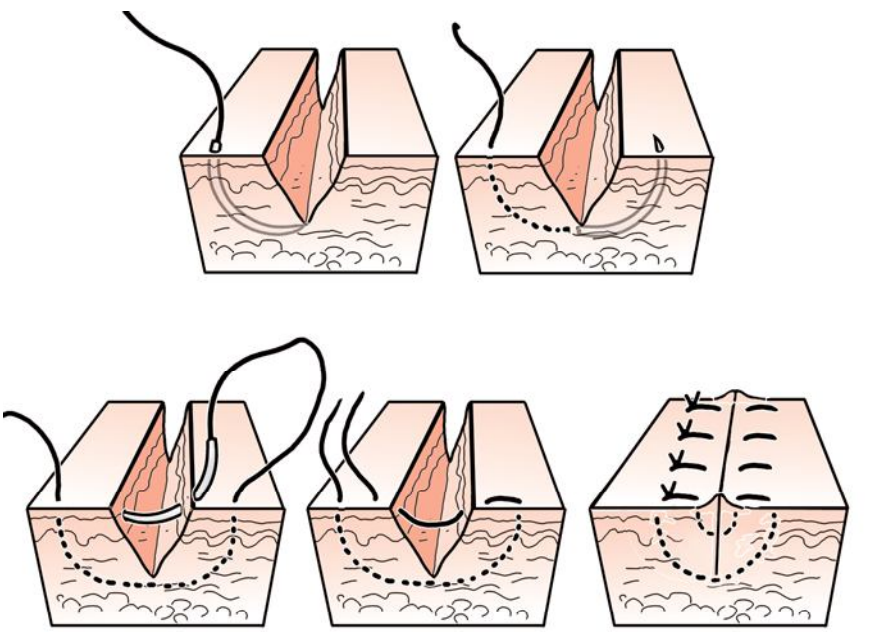
Epidermal simple interrupted sutures, used to obtain optimal alignment of the epidermal edges of the wound, are more time-consuming to place and remove than a continuous running sutures. In settings where wound healing may be impaired because of the patient's underlying medical condition or in areas of high tension, interrupted sutures may be preferred. This type of suture usually provides greater tensile strength and less potential to cause edema, induration, and impaired microcirculation than running sutures. In addition, in areas of high tension, the risk of wound dehiscence can be assessed by removing alternate sutures. If it seems that dehiscence is likely, the remaining sutures may be left in place for 3 to 4 additional days.

The vertical mattress suture provides wound-edge eversion, reduces dead space and minimizes tension across the wound (Fig 243-9). It achieves the same effect as a buried dermal suture and an epidermal suture. Because this suture requires four entry points in the skin, significant crosshatching can be expected if the suture is not removed within 5 to 7 days. This suture by nature is a tightly placed suture and can be difficult to remove because of its tendency to become embedded in the skin.

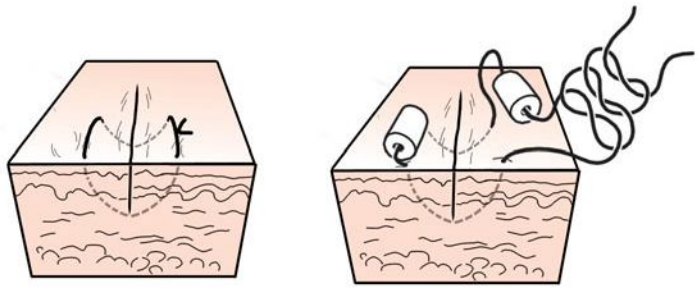
The horizontal mattress suture has been used to reduce tension across wound closures that are under significant tension (Fig. 243-10). This technique also creates wound eversion. This suture can be placed as an initial tension-reducing or holding suture and to bring the wound edges closer together, so that subcutaneous sutures can be placed to distribute tension and close the wound. At this point, if the tension has been adequately distributed, the horizontal mattress suture may be removed. If tension across the wound persists, the horizontal mattress suture may be left in place for a few days while early wound healing proceeds and removed before suture tracks have had a chance to form. The main disadvantage of this suture is the possibility of wound-edge necrosis as this suture can easily strangulate the dermal plexus between its limbs. This problem is minimized by taking large bites with the needle to encompass large amounts of tissue, by using bolsters, by tying the suture only as tight as necessary to accomplish the task of bringing the wound edges together, and by removing the suture as soon as possible. Before contemplating the use of a horizontal mattress suture for tension reduction, the surgeon should consider other means of reducing tension across the wound, including appropriate use of undermining and closure orientation, flaps from areas of tissue excess, preoperative or intraoperative tissue expanders, serial excisions, and subcutaneous sutures.

The half-buried horizontal mattress suture is primarily indicated for the positioning of various corners and tips including flap tips, M-plasty tips, and V-Y closure tips. It can also align the edges of tangential flaps and flaps with ischemic wound edges. The buried limb of this suture is placed in the potentially ischemic area in order to minimize interference with the dermal vascular plexus. A superficial simple interrupted suture through a flap tip may also work without resulting in increased risk of flap tip necrosis.

Running Sutures. The simple running suture can be used in situations where the wound edges are of equal thickness without tension, closely approximated, and with an absence of subcutaneous



▲ **FIGURE 243-9** Vertical mattress suture.



▲ **FIGURE 243-10** Horizontal mattress suture.

dead space. This suture is most useful for wounds that have already been closed by buried sutures, for the attachment of full-thickness or split-thickness skin grafts, and in areas of thin skin such as the eyelids, ears, neck, and scrotum. By eliminating all but two knots, there is less suture material resting against the skin, resulting in the development of fewer scars from suture marks. However, fine adjustments along the suture line are difficult to make and the suture has a tendency to pucker when very lax and thin skin, such as eyelid skin, is being sutured. In thin skin, the knots at each end may be tied over small bolsters to prevent them from cutting into the tissue.

The running locking suture is a variant of the simple running suture in which, after the placement of each loop, the needle is passed through the previous loop prior to starting the next loop. It is intended for the closure of well-vascularized wounds under a moderate amount of tension. The wound edges should be stiff and of equal thickness without a tendency for inversion. It is stronger than a simple running suture. However, if it is placed too tightly or if significant post-operative swelling develops, tissue strangulation with wound-edge necrosis may ensue.

The running subcuticular suture is a buried running suture which is usually not absorbable. It is ideal for the closure of wounds in areas such as the trunk and extremities where the suture must remain in place for more than 7 days. As the suture is buried, there are no suture marks and the suture may be left in place for several weeks, even months. When absorbable suture material is used, it may be left in place until it is absorbed. As this suture is capable of only modest wound-edge alignment, it should be reserved for wounds in which the tension has been eliminated with deep sutures and the wound edges, of approximately equal thickness, are closely approximated. The running subcuticular suture should be placed with a nonreactive monofilament suture such as polypropylene to facilitate suture removal and prevent suture breakage within the wound. Some surgeons use a permanent suture left in place indefinitely, as this can reduce scar stretching. If non-absorbable sutures are selected clear, nonreactive suture material should be used.

SUTURE REMOVAL Timing of suture removal must balance two factors: leaving the sutures in place long enough to allow wound healing and prevent dehiscence and removal before the development of suture track marks along the scar line. These suture track marks occur because re-epithelialization occurs around the suture. In general, the less blood supply to an area and the greater the tension across a wound, the longer the sutures should be left in place. On the face and ears, most skin sutures should be removed within 5 to 7 days. Eyelid sutures can be removed in 3 to 5 days. Neck sutures should be removed in 7 days and scalp sutures in 7 to 10 days. On the trunk and extremities, risk of wound dehiscence takes precedence over suture marks. Sutures on the trunk and upper extremities should be left in place for 7 to 14 days. Lower extremities may require up to 21 days of suture support, though, with proper deep suture placement, epidermal sutures can generally be removed in 7 to 10 days.

Absorbable sutures are not removed, but some patients develop suture reactions, consisting of sterile suture abscesses and suture extrusion through the wound. If this happens, the suture should be picked up carefully with small forceps and cut out of the wound. Any purulent material should also be drained.

STAPLE CLOSURE Staple closure of wounds is an alternative to suture closure. The staples have the advantage of very quick placement, minimal tissue reaction, and very strong wound closure. Staples are most often used with long wounds, especially on the scalp, where the suture line is hidden by scalp hair. Potentially contaminated wounds that are closed with staples appear to be more resistant to infection than wounds closed with sutures. Staples provide efficient wound closure; but when exact wound-edge alignment is required, sutures should be used. Staples are easily removed with a staple remover.

Postoperative Care

Most wounds can be cleaned appropriately with tap water and mild soaps. A diluted ascetic acid solution can be helpful to prevent *Pseudomonas* infection in sites predisposed to this. Small amount of hydrogen peroxide can help débride wounds that have developed significant crusting and exudate. However, in large amounts, it can be toxic to new cells. Most wounds are also best dressed with petrolatum and nonstick dressing. Petrolatum is relatively inert, nontoxic, nonsensitizing, and nonirritating. Although not common knowledge for the layperson, it has been well proven for years that covered or occluded wounds re-epithelialize and heal faster than dry wounds.[8] There is a large risk for allergic contact dermatitis with topical antibiotics, and they have not been shown to be superior in preventing wound infections. For wounds with significant drainage, dressings such as gauze, foam dressings, or alginates provide absorption.

CHAPTER 244

Excisional Surgery and Repair, Including Flaps and Grafts

June K. Robinson

EXCISIONAL SURGERY

Elliptical or fusiform excision is one of the most frequently performed dermatologic surgery procedures. Mastery of elliptical excision and closure is fundamental to more advanced procedures. The elements to successfully perform excisional surgery include use of sterile technique; obtaining local anesthesia; planning the excision to respect the skin tension lines and/or the cosmetic units of the face; atraumatic technique in performing the incision and undermining; meticulous hemostasis and suturing; and postoperative wound care and pain control.

Patient Selection

Side-to-side closure can be used wherever there is sufficient skin laxity to allow direct closure of the defect under minimal tension without distortion or functional impairment of surrounding structures. A fusiform (elliptical) excision is indicated for the removal of small to moderate size benign or malignant neoplasms as well as for excisional biopsy. For optimal cosmetic results, the long axis of the fusiform excision should be oriented along the relaxed skin tension lines, which are generally perpendicular to the muscle pull in the area.[1] Ideally, facial excisions should be placed within one of the major cosmetic units (e.g., forehead, nose, periorbital area, lips and perioral area, chin, and cheeks).[2] The boundaries of these units may be used to hide an incision by placing it at the junction of units. However, avoid crossing the boundary such as the nose-cheek concavity.

Risks and Precautions

- Inappropriate placement or appearance of incision.
- Plan the excision with the patient seated and with animation of the face if it is a facial location. On the trunk or extremities, test the skin tension by moving the area.
- Excise additional tissue to place the incision at the junction of facial cosmetic units or within rhytides.
- Excise the wound edges by cutting perpendicular to the skin surface and maintaining an even depth of resection across the base of the wound.
- Remove standing cones of redundant tissue.
- Excessive bleeding.
- Discontinue anticoagulation preoperatively.
- Meticulous hemostasis with arterial ligation of "named" arteries.
- Wound infection.
- Sterile technique.
- Atraumatic tissue handling.
- If the wound base perforates into the nasal or oral cavities, initiate prophylactic systemic antibiotics.
- Wound dehiscence.
- Immobilize the wound edges for 2 weeks after surgery.
- Use buried subcutaneous sutures and fascial plication to relieve tension on wound edges.

Patient Positioning

The procedure is planned with the patient in an upright position and with the proposed surgical area examined while in motion. Have the patient smile, show his teeth, or grimace to animate facial areas. After the excision lines are marked with a Gentian violet marking pen or similar marker, have the patient lie down on a mechanical surgical table in either the prone, supine, or lateral positions depending on the location of the lesion. It is important to have a mechanical table because patients sometimes get hypotensive during injection of anesthesia or surgery. If this happens, the table can be placed in reverse Trendelenburg position and the pulse and blood pressure are monitored.

Equipment

PROCEDURE ROOM

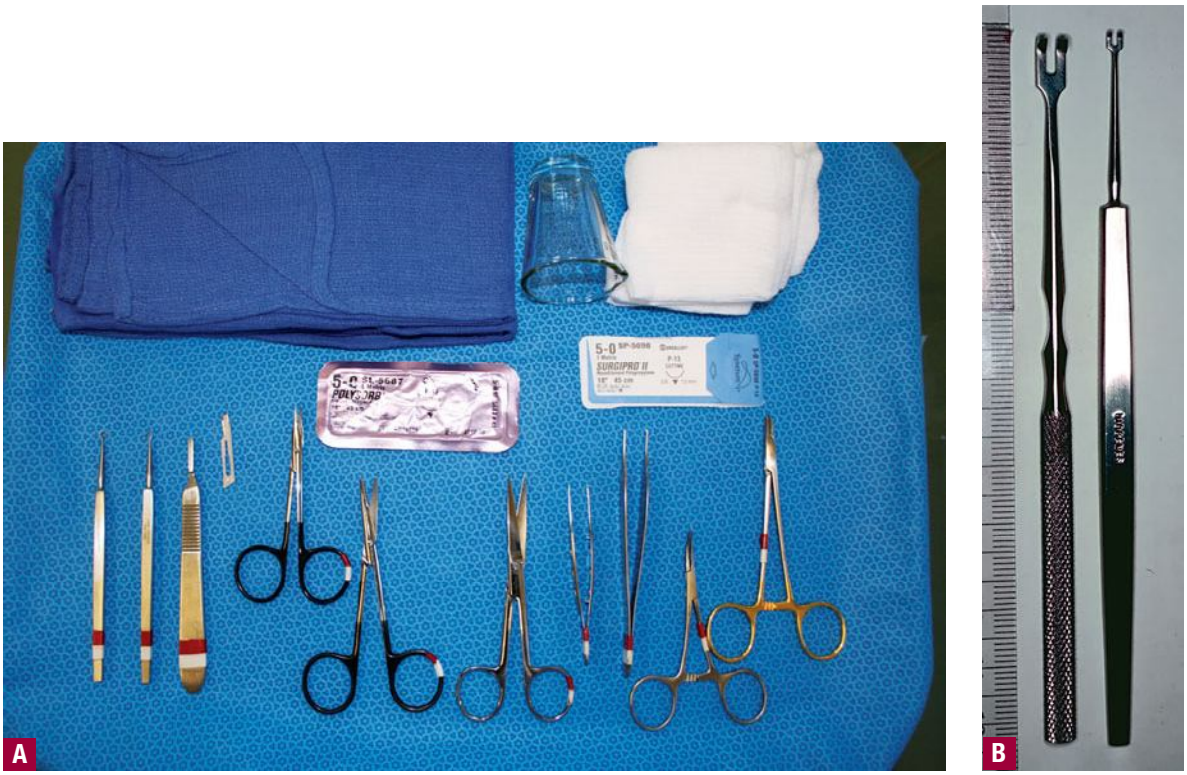
- Basic: Mechanical table, overhead procedure lights, electrocautery, ability to monitor pulse and blood pressure, Mayo stand (1 or 2), kick bucket for contaminated waste.
- Optional: Depending on the location and scope of the procedure, suction may be needed.

SURGICAL TRAY The specific instruments selected depend on the scope of the procedure and personal preference of the surgeon. It is advisable to set up the basic elements on the tray in the same "layout" each time. Consistency in placement of sharps and their return to the same location during the procedure prevents inadvertent injury with contaminated instruments to the surgeon or the assistant. One approach is to set up the tray with the instruments that are used first on the front left. After returning a used instrument to its place on the tray, the surgeon then progresses across the front of the tray (Fig. 244-1A). This leaves the back of the tray for sharps, which may be placed in a sterile cup or inserted into a disposable foam pad.

The surgeon and assistant need to coordinate their movements and should not reach across each other's field on the

EXCISIONAL SURGERY AT A GLANCE

- Elliptical excision is the most frequently performed procedure. Mastery of elliptical excision and closure is fundamental for more advanced procedures.
- Lazy S-repair, partial closure, and staged excisions are variations of the ellipse.
- Random pattern flaps, advancement flaps, subcutaneous island pedicle flaps, rotation flaps, and transposition flaps are procedures that are used when the excision wound cannot be closed by simple approximation of the wound edges.
- Full thickness and split thickness skin grafts are used when excisional wounds are either small, shallow, or when the anatomic site or general condition of the patient preclude any of the flap procedures.
- Depending on the size, surgical wounds can also be left to heal by second intention, but this may lead to wound contraction and requires prolonged healing time.



▲ **FIGURE 244-1** **A.** The basic surgical tray has the instruments laid out from left to right, and the disposable supplies are added at the back of the tray. **B.** Small two-prong skin hook has enough space between the two prongs to allow a needle to pass.

tray during the procedure. Some prefer to set up the surgeon on one Mayo stand and the assistant on another. All instruments are returned to the tray during surgery. Avoid placing instruments on the sterile surgical field when they are not in use. They will slide onto the floor or may stick the patient. Contaminated sponges should be discarded directly into the waste bucket and not placed on the tray. Used sponges discarded onto the tray cover sharp instruments and may cause inadvertent harm to personnel who are stuck with contaminated "sharps."

A basic excisional surgery tray should contain

- Instruments: #15 blade, #3 Bard-Parker scalpel handle, smooth-toothed Adson forceps, 2×1 toothed Adson forceps, two, 2-prong skin hooks, undermining scissors, two curved hemostats, suture-cutting scissors or stapler remover, small cup for sterile water to irrigate the wound
- Disposable material: Marking pen, gauze sponges, cotton tip applicator sticks, scratch pad for electrocautery tip, electrocautery tip, surgical drapes, foam pad for discarded needles
- Suture or staples

For larger procedures, such as flaps, additional hemostats are needed. Special procedures will need other instruments added to this tray [e.g., split-thickness skin grafts (STSGs) require a dermatome]. The specific instruments selected depend on the scope of the procedure and personal preference of the surgeon. The double-pronged small skin hook provides greater stability of the wound edge than the single-prong hook when the middle finger of the non-dominant hand places gentle pressure against the skin surface to evert and lift the edge (see Fig. 244-1B).

Anesthesia

Most excisions are performed with local anesthesia, usually 1 percent or 2 percent lidocaine with epinephrine 1:100,000, injected in a ring around the lesion. For larger procedures, such as rotation flaps, nerve block anesthesia is helpful because a large area can be anesthetized with a limited volume of anesthesia. Tissue distortion is limited with nerve block anesthesia, and the vascular perfusion of the flap is not impaired.

Technique

EXCISION WITHOUT CLOSURE The lesion is excised as a circle with adequate margins and the wound is allowed to heal by second intention.[4] The incision through the skin is performed at an inward sloping angle to provide exposure of the base of the wound. The diameter is usually larger than 1 cm. For patients who are poor surgical risks for reconstructive surgery or who refuse reconstructive surgery, these wounds may heal by second intention. Healing by second intention is also indicated for infected wounds, to allow observation of the wound bed after resection of tumors at high risk for recurrence, for selected pathologic ulcers, and when the anticipated cosmetic result is at least as good as that achieved by reconstruction.[5] Wounds that are allowed to granulate are very resistant to infection and cannot form a hematoma.

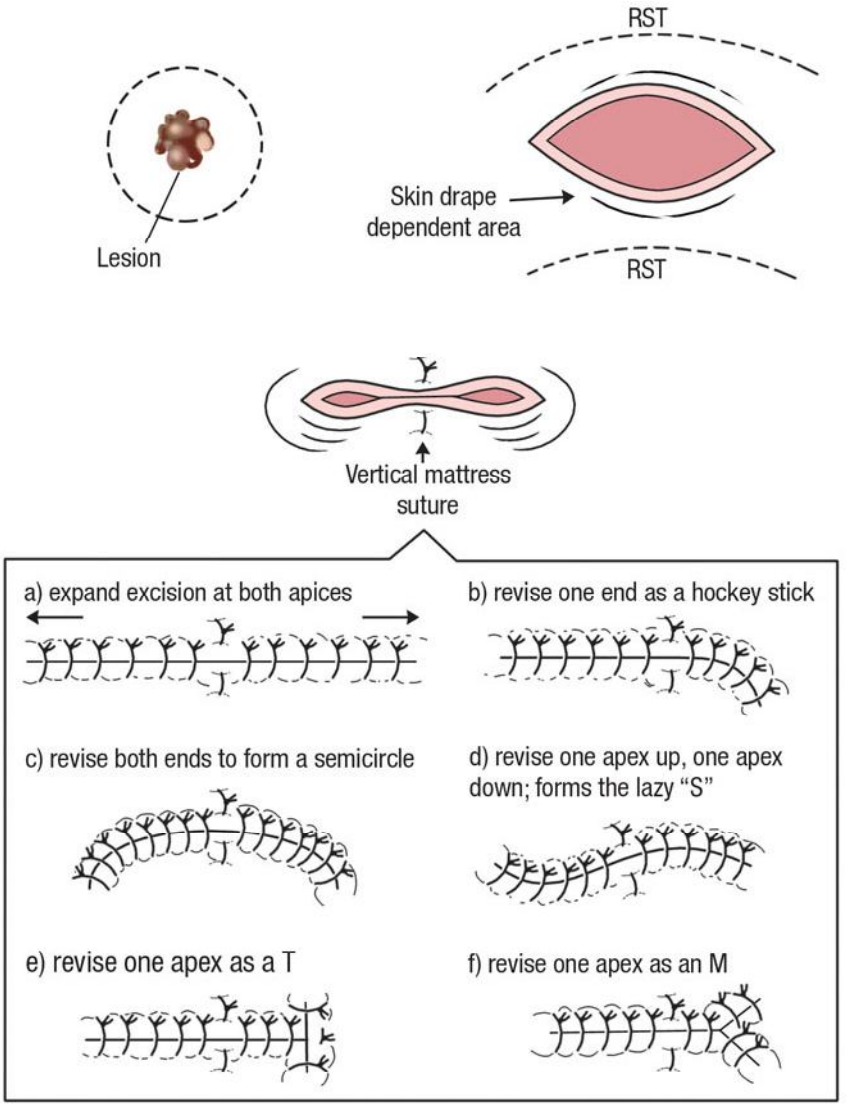
The locations that lend themselves best to wound healing by second intention, with superior cosmetic results, are concave areas such as the nose-cheek junction, medial canthus, ear concha, preauricular cheek, and retroauricular scalp.[5] Wounds allowed to heal by second intention may decrease in size as much as 50 percent or more.[5] Superficial wounds heal with less wound contraction, because there is less deposition of collagen. Therefore, a superficial wound, even on a convex surface such as the forehead or the nose, usually heals well. Because all wounds contract to some degree, it is important that there be no

"free" margin along one side of the wound that can be pulled up during wound contracture and cause distortion at the site. This may be encountered along the eyelid margins, ear margins, eyebrow, nasal ala, and lip vermillion border. These areas are better managed with appropriate reconstructive surgery.[6] Disadvantages of healing by second intention include prolonged healing time of several weeks, the need for daily wound care by the patient, and the somewhat unpredictable cosmetic results.[7]

ELLIPTICAL EXCISION ***Planning the Excision.*** If relaxed skin tension lines are not obvious, testing skin movement between the surgeon's index finger and thumb indicates the direction of least tension. After identifying the relaxed skin tension lines, draw the appropriate margins around the lesion and then design the ellipse.

When the pinch testing for skin tension lines does not help, identify the relaxed skin tension lines, and then a two-step procedure may be used. With the patient prone, supine, or in a lateral position that offers the best exposure of the site, the lesion is excised to the depth of the fat with an appropriate margin. The defect will gape open in the form of a partial ellipse, reflecting the actual relaxed skin tension lines. As the wound is closed with a few centrally placed sutures, bilateral standing cones of excess tissue form on either side of the central closure. After these standing cones are excised as dog-ear excisions, a straight-line, crescentic, lazy S-closure, M-plasty, or A-T plasty results (Fig. 244-2).

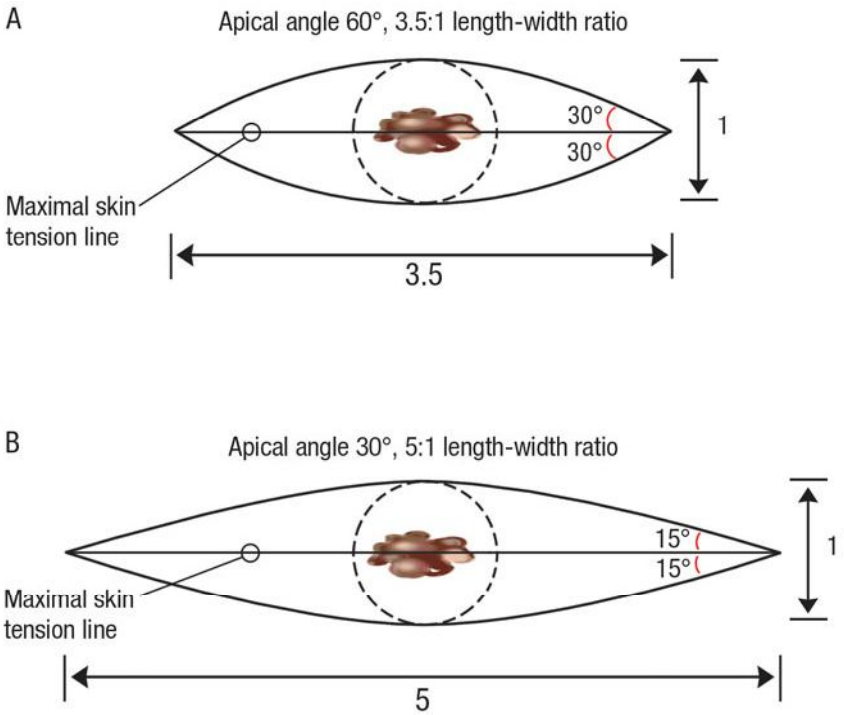
The simple ellipse is based on an optimal length to width ratio of 3.5:1.0, which may be increased to 4:1 or greater in locations with less tissue distensibility or decreased to 3:1 in areas of greater tissue distensibility. The apical angle between the two arciform incisions is in the range of 53° to 74°.[8] At the apex, each fusiform incision forms approximately a 30° angle with the intended closure line along the maximal skin tension line; thus, the two 30° angles formed at the apex by the intersection of the arciform incision lines and the line of maximal skin tension make the angle between the two arciform incision lines approximately 60° for an ellipse with approximately a 3.5:1.0 ratio (Fig. 244-3A). As the ratio becomes larger, the apical angle decreases; thus, for a ratio of 5:1, which may be needed for scalp surgery, the apical angle approaches 30° (see Fig. 244-3B).



▲ **FIGURE 244-2** When the lesion is excised with an appropriate margin, the resulting defect is often circular. By pinching the wound edges together in several ways, standing cones of redundant tissue are manipulated to form in the direction in which they may be excised with optimal scar placement. The incision is extended in a) a straight line; b) on one end in a hockey-stick revision; c) on both ends by two hockey-stick revisions in the same direction, creating a curved incision; d) on both ends by two hockey-stick revisions in the opposite direction, creating a lazy-S incision; e) at one end of the incision both inferior and superior to the incision, creating a T incision; or f) at one end of the incision both inferior and superior to the incision, creating an M incision.

Procedure. After the surgical site is marked with the lines of excision, the field is anesthetized, prepped, and draped. The incision is made smoothly by starting with the tip of the blade at the apex. Then, as the hand moves toward the middle or arc of the incision, the blade is allowed to rock down onto the belly of the blade. As the apex of the incision is approached, the blade rocks up onto its tip, which allows the surgeon to clearly see the apex of the incision under the advancing hand (Fig. 244-4). This prevents "overshooting" the incision beyond the planned apex. Another important point is that the scalpel is held perpendicular to the skin surface, which prevents undercutting the lesion to produce a beveled incision. In general, a #15 blade is used to cut through to the fat on the first pass; however, thick back skin may require a #10 blade. Traction on the surrounding area is needed to prevent bunching of the tissue ahead of the pressure exerted by the blade.

The size of the defect produced by the incision is determined by the size of the lesion and the necessary margin of resection. When benign lesions are excised with a 1- to 2-mm margin (Fig. 244-5), the margin for malignant lesions ranges from 5 mm to 2 cm (Fig. 244-6).



▲ **FIGURE 244-3** **A.** At the apex, each fusiform incision forms approximately a 30° angle with the intended closure line along the maximal skin tension line. **B.** As the length-width ratio becomes larger, the apical angle decreases; thus, for a ratio of 5:1, which may be needed for scalp surgery, the apical angle approaches 30°.

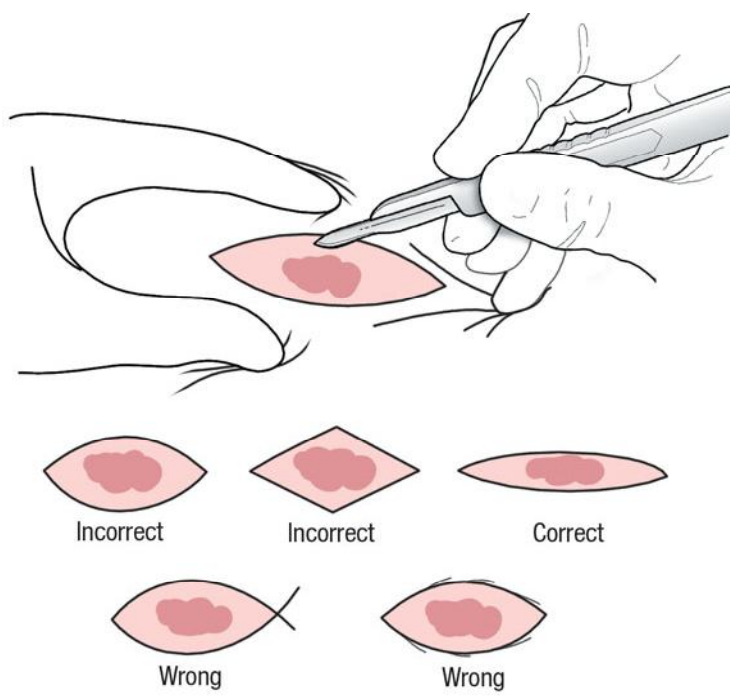
The end of the ellipse is grasped gently with a toothed forceps to elevate the tissue. The base of the specimen is dissected in an even plane with a scalpel for sharp dissection or a scissors for blunt dissection. The apex of the fusiform excision should be the same depth as the middle. There is a tendency to excise the tips at a more shallow depth than the center. When the depth of the excision is not uniform, a bulge, a standing cone of tissue, surrounds the tip as the wound is closed with subcutaneous sutures. These standing cones are excised so that the force of the redundant tissue does not exert pressure against the wound closure, and to improve the final appearance of the closure.

Once meticulous hemostasis is obtained at the base of the excision, then undermining of the surrounding skin and a layered closure are performed. Undermining with a blunt-tipped scissor is needed to allow placement of buried subcutaneous sutures and to minimize tension on the wound. If the skin around the surgical site is lax, and subcutaneous sutures can be placed without undermining, then it is appropriate to do so. Patients receiving anticoagulants or with reduced platelets benefit by limiting the extent of undermining as the risk of bleeding and hematoma formation is decreased.

Wound Closure. Most wounds are closed with a double layer of closure consisting of absorbable deep sutures and nonabsorbable superficial sutures. A wound gains only 7 percent of its final strength after 2 weeks.[8] As most skin sutures are removed within 1 week of placement, absorbable buried sutures are used as part of layered wound closure. This provides support for the wound until tensile strength has increased sufficiently to prevent wound dehiscence. Deep, buried sutures are placed into wounds to reduce or eliminate tension on the wound edges. On the trunk and extremities, where tension across wounds is greatest, the use of buried sutures may reduce the amount of scar spread. Buried sutures can align the wound edges, so that the skin edges are closely approximated even before the placement of skin sutures. Deep sutures can eliminate dead space and align deep structures such as skeletal muscle or fascia. Deep sutures can also be used to anchor overlying tissue to underlying fixed structures, such as periosteum, to maintain proper facial contour and function. This is exemplified by anchoring a melolabial flap to the maxillary periosteum.

Suturing technique, which is described in Chap. 243, reduces and redistributes wound tension, slightly everts the skin-edge, eliminates dead space, and maintains or restores natural anatomic contours, while avoiding the formation of permanent suture marks on the skin surface. When there is little tension on the wound edges, the wound is closed by the rule of halves. The first suture is placed in the center of the wound. Then each half of the remaining defect is closed in a similar manner.

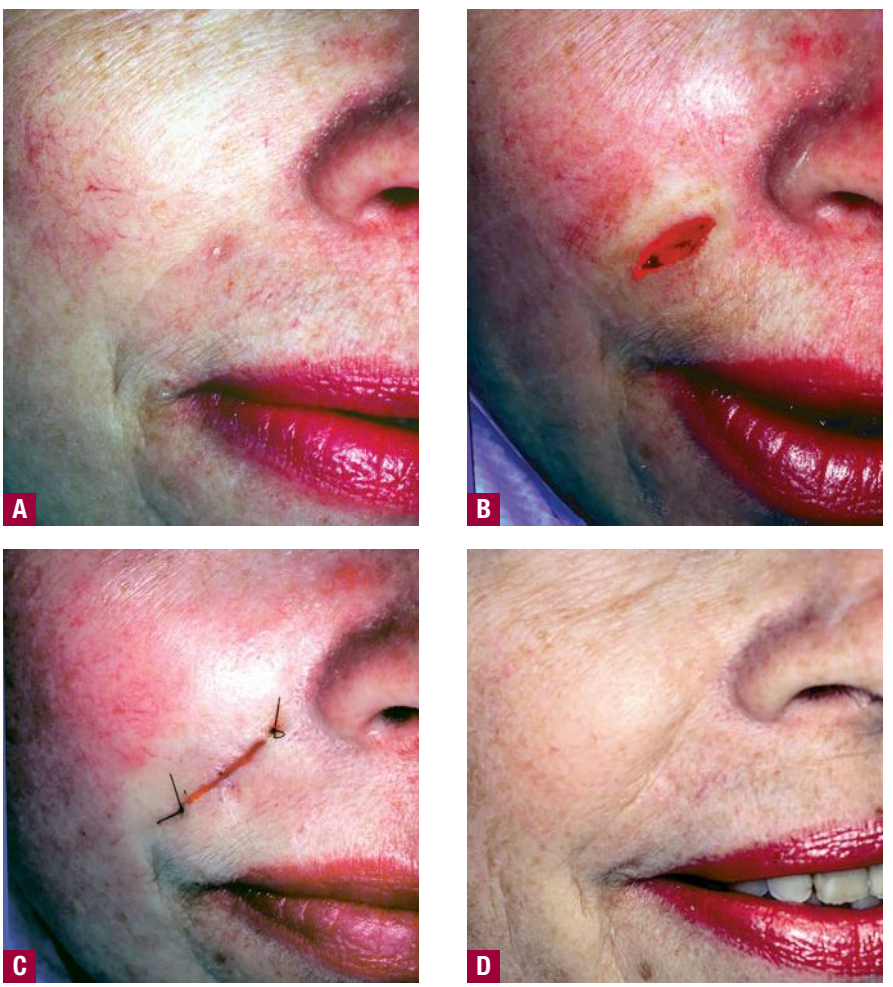
If there is a lot of tension on the wound, a vertical mattress retention su-



▲ **FIGURE 244-4** The incision is made smoothly by starting with the tip of the blade at the apex.

▲ **FIGURE 244-5** **A.** A benign hemangioma of the left lower eyelid. The incision is planned to lie at the junction of the periorbital area and the cheek. **B.** The closure produces a mild eversion of the lower lid due to the volume of local anesthesia. **C.** Six months after surgery.

ture across the middle of the wound may put the tissue on stretch. The retention suture does not close the edges. Then, the wound closure begins at the apices and progresses to the middle of the wound. This helps to reduce the tension as the repair advances from the ends to the middle of the defect. Once the wound is closed, the retention suture is removed. The suture line is cleansed and then checked to be sure there is no active bleeding. A gauze pad or cotton-tipped applicator is rolled along the suture line. Minimal oozing is often present on the first roll but disappears with subsequent rolls. If there is bleeding, then firm downward pressure is applied to the wound with gauze for 5 minutes by the clock. If bleeding persists, then the sutures are removed, and the wound bed is explored for the source of the bleeding.



▲ **FIGURE 244-6** **A.** A primary basal cell carcinoma of the right nasolabial fold was previously biopsied by the shave technique. **B.** The excision with 5-mm margins is planned as an ellipse that lies in the nasolabial fold. **C.** Closure under minimal tension with buried subcutaneous sutures and a pullout suture. **D.** Ten years after surgery.

Suture Removal. The risk of crosshatch marks across the suture line can be minimized by removing the sutures within 5 to 7 days before the formation of epithelial suture tracks is complete, using minimally reactive monofilament suture, such as polypropylene, and eliminating tension across the wound with appropriate planning of wound closure, adequate undermining, and the use of buried sutures. On the face and ears, most skin sutures should be removed within 5 to 7 days, with eyelid sutures removed in 3 to 5 days. Neck sutures should be removed in 7 days and scalp sutures in 7 to 10 days. On the trunk and extremities, risk of wound dehiscence takes precedence over suture marks. When the closure is under extreme tension or the edges are not approximated with subcutaneous sutures, sutures on the trunk and extremities should be left in place for 10 to 14 days to provide additional support.[10] If the wound edges are easily approximated with subcutaneous sutures, then they may be removed in 7 days. If the wound edges are everted by the subcutaneous sutures, then cyanoacrylate may be applied to the skin surface. This approach provides easy wound care and the patients does not have to return for suture removal.

Simple interrupted sutures are more time-consuming to place and remove than a running suture. In settings where wound healing may be impaired due to the patient's advanced age or underlying disease, interrupted suture techniques may be preferred, as interrupted sutures may have, with all other factors being

Box 244-1

Excisional Surgery with Primary Closure Patient Instructions

1. Immediately after surgery, you may apply an ice pack intermittently to the wound area for 15 minutes on and 5 minutes off over a period of 2 hours.
2. Elevate the area for __ days after surgery.
3. Take acetaminophen, ____ mg three times a day for 48 hours after surgery if needed.
4. If you develop pain at the site of surgery, call the doctor at _____.
5. Do not remove the dressings or get them wet for 24 to 48 hours.
6. You may shower in 48 hours but do not let the water directly pound on the area of the surgery. After showering, change and replace the dressing with a nonstick pad and paper tape.
7. In the first 48 hours after surgery around the eyes or on the forehead, the eyes may be swollen almost shut.
8. If you have blood trickle out from under the bandage as a stream of blood, apply direct downward pressure for 15 minutes. If the bleeding stops, in the A.M., call the office to be seen for a dressing change. If the bleeding does not stop, go to the emergency room.

CHAPTER 245

Mohs Micrographic Surgery

Ken K. Lee
Valencia D. Thomas
Neil A. Swanson

Mohs micrographic surgery (MMS) is a precise method of treating skin cancer that results in the highest cure rate with maximal tissue conservation. Developed by Dr. Frederic E. Mohs, the procedure combines microscopic evaluation of tumor margins ("micro") with detailed mapping of the tumor orientation ("graphic"). The hallmark of MMS is tangential excision that theoretically allows 100 percent of the tumor margin to be examined by the surgeon who serves the dual roles of surgeon and pathologist. Commonly referred to as *Mohs surgery*, other names have been used to describe the procedure, including *chemosurgery*, *microscopically controlled excision*, and *microscopically oriented histographic surgery*.

HISTORY

TECHNIQUE

The MMS set up requires an appropriately equipped procedure room, well-trained nursing staff, and a laboratory with a histotechnician trained in the specialized MMS tissue processing. The latter cannot be overemphasized as the quality of the microscopic slides and the efficiency in which they are produced are paramount in order to perform MMS at its highest level.

MMS is usually performed on ambulatory patients in an outpatient setting (Fig. 245-1).[3] The tumor is initially identified, marked, and infiltrated with local anesthesia. It is then debulked using a curette, which further delineates the size. The scalpel blade is held at approximately 45 degrees to the skin surface and the tumor is excised 2 to 3 mm beyond the curetted margin, producing a saucer-shaped piece of tissue. Anatomic orientation is carefully maintained. The remaining skin edge, as well as the surface of the removed tissue, is scored to preserve this orientation. The depth of the excision usually encompasses the entire dermis but can vary depending on the depth of the curettage. The wound is bandaged and the patient waits for the processing, which usually takes 30 to 45 minutes.

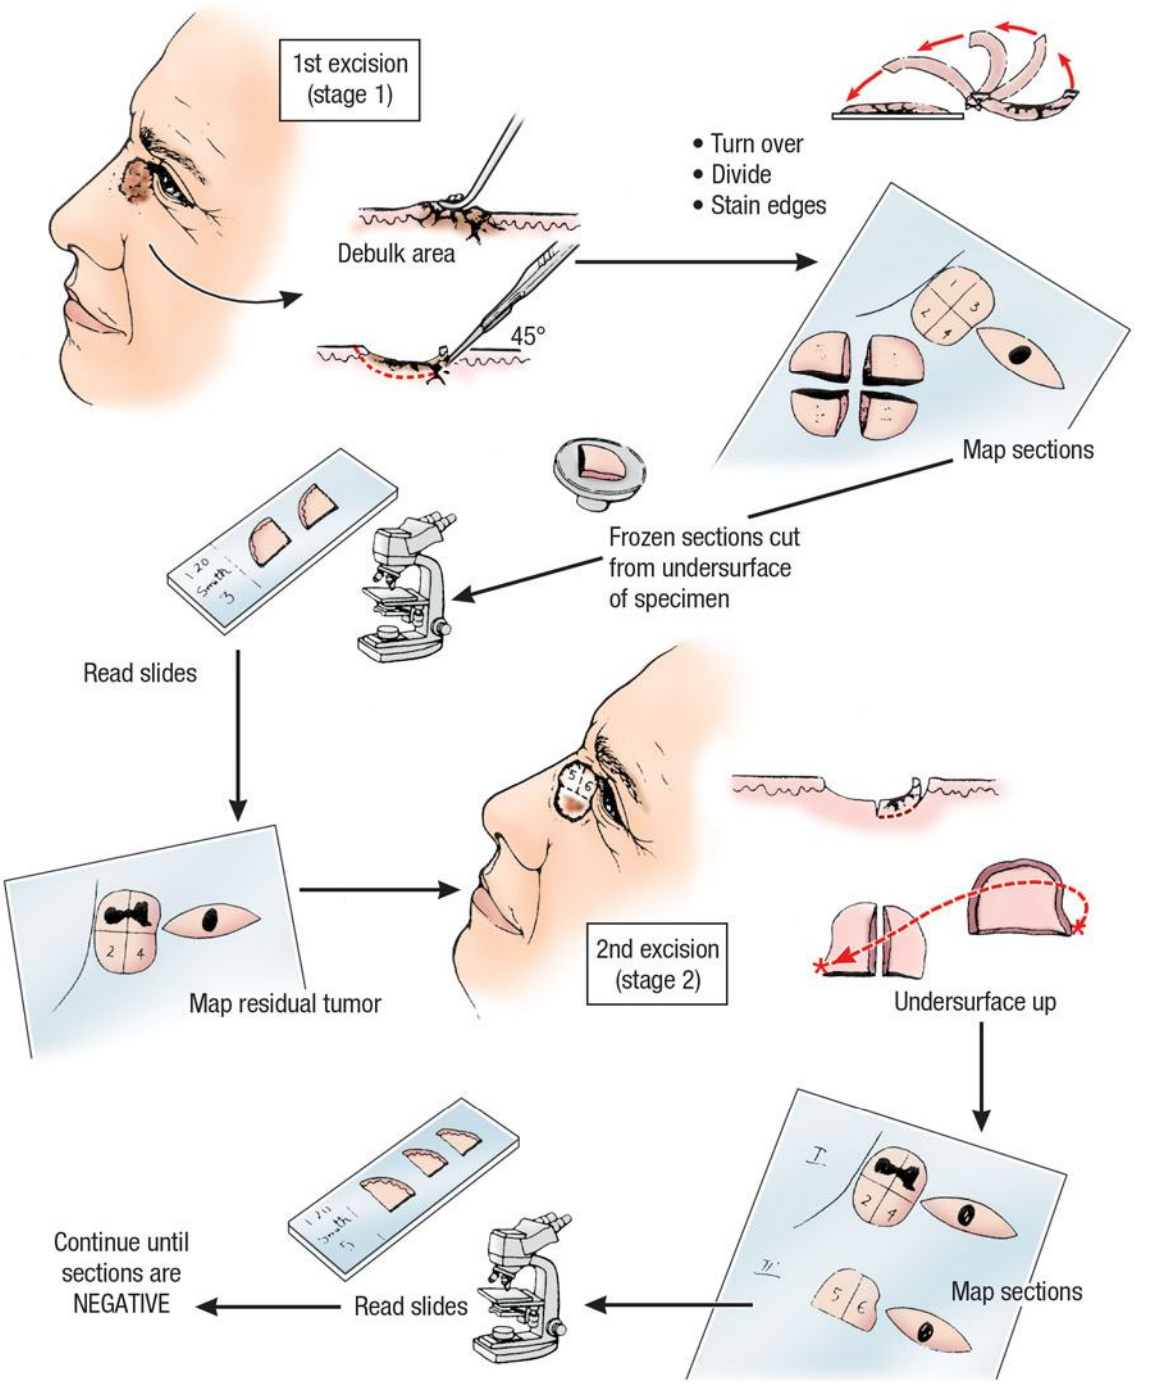
The tissue is sectioned into smaller pieces along the scored lines, turned over and inked with two to three different colors for precise orientation. An anatomic map is drawn with markings correlating with the scored lines and inked margins. The tissue is then laid flat on a cryostat chuck so that the epidermis and the deepest margin are on one plane (allowing for theoretically 100 percent of the tumor margins to be visualized). The tissue is then frozen, sectioned horizontally, placed on a slide, and stained.

A unique aspect of MMS is that the surgeon has a dual role as the pathologist, thus optimizing the clinicopathologic correlation. This leads to accuracy that is difficult to duplicate when there is a separate surgeon and pathologist. The Mohs surgeon examines the slides microscopically, correlating them with the anatomic map he or she has drawn. If there is persistent tumor on the margin(s), it is marked on the map and the patient is brought back into the procedure room for the second stage. Additional section(s) are again tangentially excised but limited only to the area(s) of persistent tumor. This process continues until the margins are tumor free.

MOHS MICROGRAPHIC SURGERY AT A GLANCE

- Mohs micrographic surgery (MMS) is a precise method of treating skin cancer that results in the highest cure rate with maximal tissue conservation.
- MMS has been used for different types of skin cancers. The overwhelming majority of the cases, however, are basal cell carcinomas and squamous cell carcinomas.
- Specific indications for MMS include (1) high risk of local recurrence, (2) need for tissue preservation, and (3) high risk of metastasis.
- Advances in processing and staining techniques have increased the speed and accuracy of tumor excision.

In comparison, with traditional excisions the scalpel blade is placed perpendicular to the skin surface, the tissue is processed in a "bread loaf" fashion and sectioned through the center of the tumor. Less than 1 percent of the tumor margin is visualized. In MMS, the goal is to visualize the outer as well as deep margins, and therefore only the tumor on the margins is represented on the



▲ **FIGURE 245-1** Schematic of Mohs micrographic surgery technique. See text for detailed explanation.

slide. The tumor in the center is not seen unless it extends to the margins.

Since the introduction of the fresh-tissue technique, MMS has been refined to an efficient, highly successful surgery. Advances in special staining techniques are further contributing to the evolution of this field. Alternatives to hematoxylin and eosin, such as toluidine blue, can be used to help accentuate the architectural findings of basal cell carcinomas (BCCs) and other cutaneous tumors.[4,5] Of particular interest is the use of rapid immunostaining in the evaluation of tumor specimens prepared with the fresh-tissue technique. Because of the difficulty in evaluating melanocytes on frozen sections, immunostains such as Melan-A/MART-1, HMB-45, and S100 have gained recent attention in the treatment of lentigo maligna and melanomas (see Chap. 124).[6–9] Other tumors, such as squamous cell carcinoma (SCC), granular cell tumor, and dermatofibrosarcoma protuberans have stimulated an assessment of other immunomarkers in MMS.[10–12] As the roles of these immunostains are more clearly delineated, their use may become commonplace in MMS.

Reconstructive surgery has become an important and integral aspect of the care of the skin cancer patient. The original chemosurgery defects healed by second intention, but the current defects that result from the fresh tissue technique permit primary side-to-side closures, flaps, and grafts (Fig. 245-2). As a result, advances in reconstructive surgery have been significant in the evolution of MMS.

INDICATIONS

MMS has been used for different types of skin cancers. The overwhelming majority of the cases, however, are BCCs and

▲ **FIGURE 245-2** **A.** Postoperative defect after two stages of Mohs micrographic surgery. **B.** Reconstruction with rhombic transposition flap.

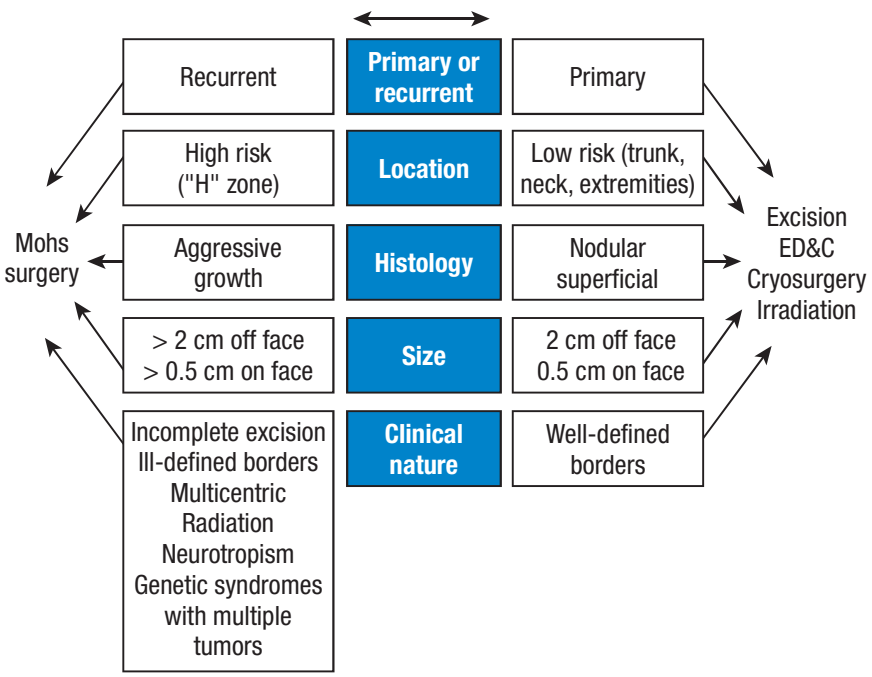
SCCs. MMS is not needed for all skin cancers and should be reserved for those cases that meet specific indications. The American Academy of Dermatology has outlined specific guidelines, which broadly include (1) high risk of local recurrence, (2) areas of tissue preservation, and (3) high risk of metastasis.[13] There are other treatment modalities such as simple excision, electrodesiccation and curettage, cryosurgery, topical chemotherapy, and irradiation that may be appropriate for other situations. Conversely, MMS should not be used as the only treatment for some complex cancers. A multi-disciplinary approach may be more appropriate for these cases.

Basal Cell Carcinoma (See Chap. 115)

Although the potential of BCC for metastasis is very low, it can cause significant local destruction. Four important factors that determine the successful treatment of primary BCCs are histologic characteristics, location, size, and clinical nature (Fig. 245-3). Histology ranges from less-aggressive patterns, such as nodular and superficial, to more-aggressive patterns, such as infiltrative, micronodular, and sclerosing (morpheaform). Perineural involvement also constitutes an aggressive pattern. The aggressive subtypes typically are more ill-defined clinically with less predictable radial growth patterns leading to a greater subclinical extension of tumor. When viewed in the traditional "bread loaf" fashion, these areas of tumor extension can be missed leading to a false-negative result.[14] MMS is ideally suited for visualizing these extensions as close to 100 percent of the margins are inspected.

BCCs located on the ear, nose, eyelid, and lip are part of the "H" zone where MMS is indicated because of the high recurrence rate (see Chap. 115; see eFig. 245-3.1 in on-line edition).[15] In these locations, tumors tend to be more destructive and invasive and are in close proximity to vital structures. Tumors spread along perichondrium, periosteum, perineurium, and fascial planes. They also spread along embryonic fusion planes to unexpected depths in areas such as the nasal ala/nasolabial fold junction, preauricular sulcus, and columella, as well as penetrating deeply in areas such as the medial canthus where there is minimal deep structural support. Furthermore, MMS is important in maximally preserving normal tissue in these cosmetically and functionally sensitive regions.

Size and clinical nature are also important considerations in determining the appropriate treatment. BCCs greater than 2 cm are more likely to recur or be incompletely excised. Ill-defined clinical borders also make simple excisions more difficult.[16] Overall, MMS has a 99 percent cure rate for primary BCCs, compared with 91.3 percent for



▲ **FIGURE 245-3** Guidelines for consideration for Mohs micrographic surgery. The right side of the figure represents less-aggressive presentations of basal cell carcinomas that can be treated with standard treatment regimens. The left side of the figure represents more aggressive presentations for which Mohs micrographic surgery should be considered. ED&C = electrodesiccation and curettage.

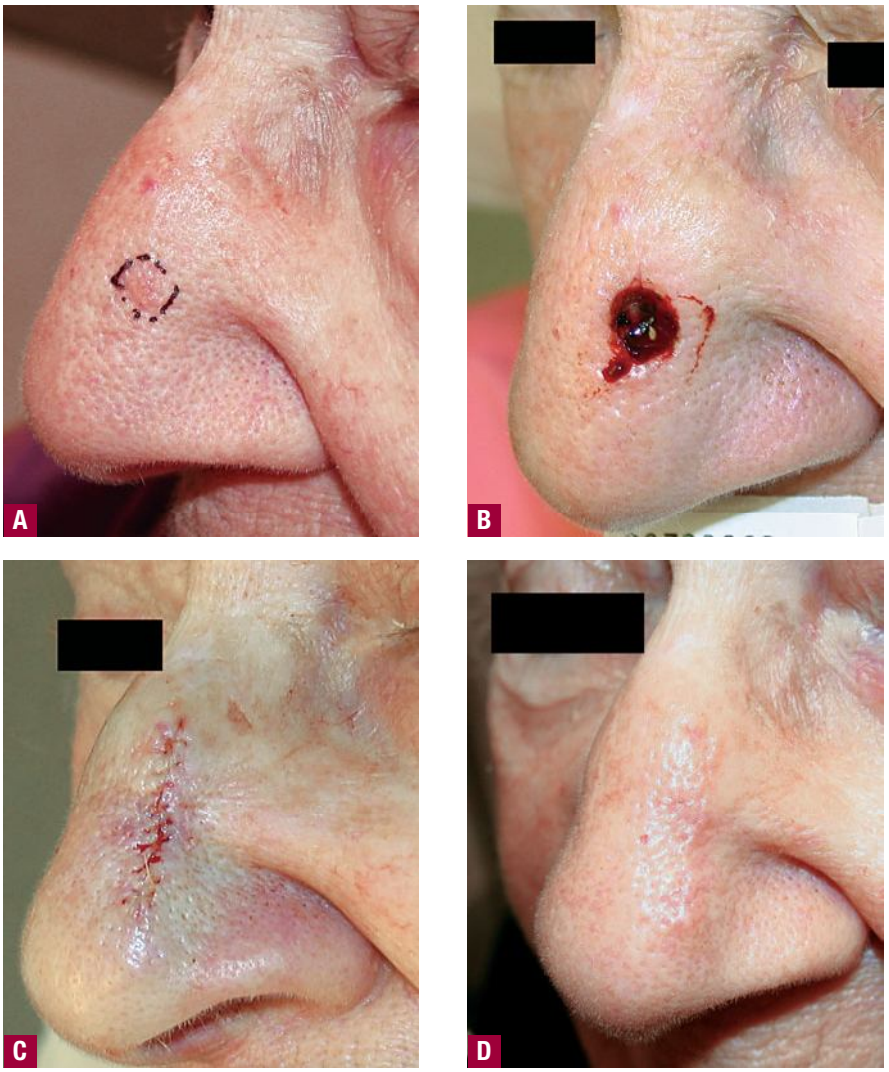
all other treatment modalities previously mentioned.[17] Figs. 245-4 and 245-5 demonstrate the procedure and its outcome.

Beyond primary BCCs, MMS is advantageous in the treatment of incompletely excised and recurrent BCCs. MMS is indicated irrespective of histologic sub-types or location since the prior treatment modalities have already failed. On the face, incompletely excised BCCs recur between 12 percent and 41 percent of the time if left untreated.[18] These can be readily treated with MMS by narrow margin excision around the previous scar. This results in precise localization of the persistent tumor.

Recurrent BCCs, by their very nature, are more aggressive and difficult to treat. Clinically, they can be subtle and therefore the diagnosis is usually delayed. By the time the recurrence is noted on the skin surface, there may be large tumor burden buried in the scar. For these recurrences, MMS yields the best cure rate of 94.4 percent, compared to all other modalities, which average only 80 percent.[19]

Squamous Cell Carcinoma (See Chap. 114)

Although SCCs and BCCs are treated similarly, it would be inadvisable to think that they are biologically the same. SCC metastasizes at a much higher rate and accordingly has a higher mortality rate. The indications for MMS are similar to BCC, but additionally involves identifying and reducing the risk for metastasis. As with BCC, histologic pattern is important in determining the potential aggressiveness. Tumors that are poorly differentiated and/or have perineural involvement have a worse prognosis. Locations such as the ear, penis, lip, and digits, lesions greater than 2 cm, deeper lesions, and those occurring in scars carry a higher risk of metastasis and local recurrence. Five-year cure rate for primary SCC of the skin is 96.9 percent with MMS versus 92.1 percent for all other modalities combined (irradiation, curettage and electrodesiccation, and excision). The difference is greater for primary SCCs of the lip (97.7 percent vs. 89.5 percent) and ear (94.7 percent vs. 81.3 percent). For recurrent tumors, cure rate is 90 percent with MMS versus 77.7 percent with excision.[20] Immunosuppressed transplant patients have a disproportionate number of SCCs and also carry a greater risk of more aggressive disease.



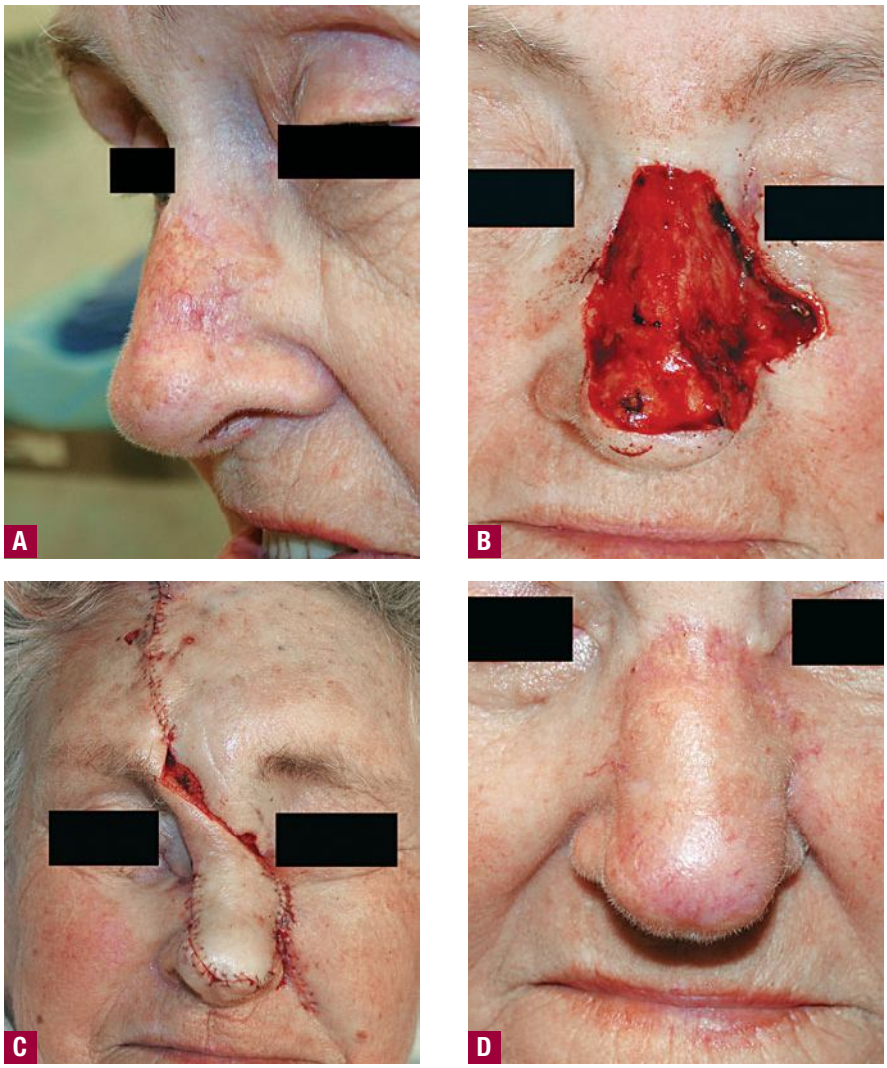
▲ **FIGURE 245-4** Defects may resemble the clinical lesion. Mohs micrographic surgery is helpful to delineate a narrow margin. **A.** Preoperative image of this biopsy-proven basal cell carcinoma. **B.** Final defect after Mohs-assisted excision. **C.** Repair of the defect with a complex linear layered closure. **D.** Two-month follow-up.

MMS is an integral part of SCC management and can be especially valuable in special situations such as tracking perineural involvement. It is important to note, however, that radiation therapy and surgical lymph node assessment may also be needed for proper management of more aggressive disease.

Melanoma (See Chap. 124)

MMS for treatment of melanoma is controversial. Two issues have given rise to this controversy: interpretation of melanocytes by frozen section and determination of proper excision margins for melanoma. Some believe that MMS is most useful for lentigo maligna type melanoma in situ on the head and neck region, which is notorious for significant sub-clinical spread that often extends beyond the standard recommended excision margins. Although there have been reports of successful treatment of melanoma with MMS, the variability in the frozen section quality and interpretation places a limit on consistency and accuracy. The method that is commonly used at some centers is a modified MMS in which a 2- to 3-mm margin is excised beyond the final frozen section margin and submitted for permanent paraffin embedded sections. These sections are processed in the MMS style so that 100 percent of the peripheral margins are visualized. The obvious disadvantage of this method is significant increase in the turnaround time delaying the final closure of the wound.[21,22]

A newer method that potentially improves both the speed and accuracy is



▲ **FIGURE 245-5** Mohs micrographic surgery is helpful in determining the subclinical extension of tumors. **A.** Preoperative image of a morpheaform basal cell carcinoma. **B.** Mohs micrographic surgery reveals extensive sub-clinical involvement of the tumor. **C.** Repair of the defect with a paramedian forehead flap. **D.** Two-month follow-up.

the use of immunohistochemistry stains. S100 and HMB-45 have traditionally been used to mark melanocytes with variable sensitivity and specificity. Melan-A is a newer addition with better consistency and easier interpretation.[23] Although the turnaround time is shorter than with paraffin sections, it is still more labor intensive than traditional hematoxylin and eosin–based frozen sections. Long-term studies determining efficacy are still needed.

Other Cutaneous Malignancies

MMS has been used to treat a wide range of cutaneous malignancies. The consensus indications outlined by the American Academy of Dermatology include verrucous carcinoma, keratoacanthoma, dermatofibrosarcoma protuberans, atypical fibroxanthoma, malignant fibrous histiocytoma, leiomyosarcoma, adenocystic carcinoma of the skin, sebaceous carcinoma, extramammary Paget disease, erythroplasia of Queyrat, oral and central facial paranasal sinus neoplasms, microcystic adnexal carcinoma, apocrine carcinoma of the skin, certain aggressive locally recurrent benign tumors, and Merkel cell carcinoma. All cutaneous malignancies that exhibit a contiguous pattern of radial growth and that can be interpreted on frozen section should theoretically be amenable to MMS.

MMS is cost-effective although it should be reserved for those cases that meet appropriate indications.[24] It is a highly technical procedure that requires meticulous attention to detail and considerable training and experience to achieve the expected high cure rates.

CHAPTER 246

Nail Surgery

Robert Baran

The main objectives of nail surgery are to aid diagnosis by biopsy, to treat infection, to alleviate pain, to remove local tumors, and to ensure the best cosmetic results in acquired and/or hereditary and congenital abnormalities.

PATIENT SELECTION

Providing the patient with an exact illustration of the operation is helpful to give the patient insight into the procedure and its expected outcome. A thorough discussion regarding postoperative morbidity is essential.

RISKS AND PRECAUTIONS

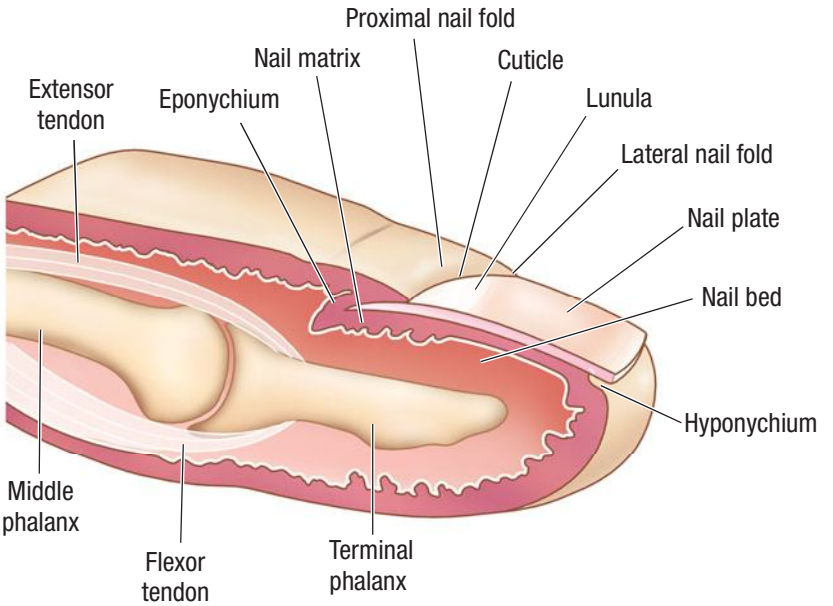
Factors to be considered include the following:

- History of systemic disease
- History of allergies
- Concomitant drug use

Preoperative photographs as well as any taken during surgery may be useful medicolegally. Careful history taking may reveal systemic disease such as diabetes mellitus, blood dyscrasia, vascular disease, vascular collagen disease (scleroderma), allergy, chronic pulmonary disease, or immune impairment. Any of these may at times be contraindications to surgery or may call for alteration of the technique to be used. Surgery of the nail is not recommended in patients with high-risk conditions. A history of concurrent use of drugs may be relevant, because these drugs may affect anesthesia (e.g., monoamine oxidase inhibitors or phenothiazines), prolong bleeding (e.g., aspirin and anticoagulants), delay healing (e.g., glucocorticoids), or have toxic effects on the nail apparatus (e.g., retinoids). There may be a history of allergy to lidocaine or mepivacaine or to parabens contained in both as a preservative. A knowledge of previous antitetanus immunization is important, because administration of tetanus toxoid may be advisable in association with surgery involving the toenail or traumatic lesions that come into contact with soil.

A magnifying lens may be useful to observe the color, surface, and structure of the periungual tissue and to compare the unaffected contralateral digit. It may be necessary to probe in order to localize pain, to obtain a radiograph to rule out underlying bone involvement, or to ask for ultrasonography and magnetic resonance imaging when a tumor is suspected.

The basic requirements for nail surgery include a detailed knowledge of the anatomy and physiology of the nail apparatus on the part of the surgeon. Full aseptic conditions, regional block anesthesia, and local hemostasis are indispensable.



▲ **FIGURE 246-1** Sagittal section of the nail unit.

ANATOMY[1] (See Chap. 87)

The nail plate is the permanent product of the nail matrix. Its normal appearance and growth depend on the integrity of the perionychium and the bony phalanx (Fig. 246-1). The nail is a semihard horny plate covering the dorsal aspect of the tip of the digit. The nail is inserted proximally in an invagination that is practically parallel to the upper surface of the skin and laterally in the lateral nail grooves. This pocket-like invagination has a roof, the proximal nail fold, and a floor, the matrix from which the nail is derived. The matrix extends approximately 6 mm under the proximal nail fold, and its distal portion is only visible as the white semicircular lunula. The general shape of the matrix is a crescent, concave in its posteroinferior portion. The lateral horns of this crescent are more developed in the great toe and are located at the coronal plane of the bone. The ventral aspect of the proximal nail fold encompasses both a lower portion, which continues the matrix, and an upper portion (roughly three-quarters of its length), called the *eponychium* (see eFig. 246-1.1 in on-line edition). The germinal matrix forms the bulk of the nail plate. The proximal element forms the superficial third of the nail plate, whereas the distal element provides its inferior two-thirds. The ventral surface of the proximal nail fold adheres closely to the nail for a short distance and forms a gradually desquamating tissue, the cuticle, made of the stratum corneum of both the dorsal and the ventral sides of the proximal nail fold. The cuticle seals and protects the nail cul-de-sac.

The nail plate is bordered by the proximal nail fold, which is continuous with the similarly structured lateral nail fold on each side. The nail bed extends from the lunula to the hyponychium. It has parallel, longitudinal rete ridges.

In contrast to the matrix, the nail bed has a firm attachment to the nail plate. Colorless but translucent, this highly vascular connective tissue, containing glomus organs, transmits a pink color through the nail. Avulsion of the overlying nail plate denudes the nail bed.

Distally, adjacent to the nail bed, lies the hyponychium, an extension of the volar epidermis under the nail plate, which marks the point at which the nail separates from the underlying tissue. The distal nail groove, which is convex anteriorly, separates the hyponychium from the fingertip.

The circulation of the nail apparatus is supplied by two digital arteries that

Box 246-1

- Nail elevators
- Single- or double-pronged skin hooks
- Double-action nail splitter (bone rongeur)
- Clippers, splitting scissors, English nail splitter
- Pointed scissors (Gradle scissors), curved iris scissors
- Small-nosed hemostats
- Disposable biopsy punches
- Penrose drains
- Luer-Lok syringe, 30-gauge needles

course along the digits and give off branches to the distal and proximal arches. The sensory nerves to the distal phalanx of the three middle fingers are derived from fine, oblique, dorsal branches of the volar collateral nerves. Longitudinal branches of the dorsal collateral nerves supply the terminal phalanx of the fifth digit and also the thumb.

Among its multiple functions, the nail provides counterpressure to the pulp that is essential to the tactile sensation involving the fingers and to the prevention of hypertrophy of the nail bed.

INSTRUMENTS AND DRAPING

The instruments used in nail surgery are, in general, the same as those used in cutaneous surgery with the addition of the instruments listed in Box 246-1.

Draping is accomplished by means of a sterile glove on the involved hand. The tip of the glove is cut off on the finger that is to undergo surgery. The remaining open finger of the glove is then rolled back down the digit. This exsanguinates the digit and provides a tourniquet when it reaches the proximal part of the finger. For toenail surgery, the foot is draped in the usual aseptic manner with sterile towels secured by towel clamps.

ANESTHESIA

Local anesthesia should be administered while the patient is reclining or in a supine position. Lidocaine is widely used because the incidence of allergy to this agent is very low. Because the benefit of epinephrine is still debatable, it is preferable to use 2 percent lidocaine alone. A tourniquet can provide prolonged hemostasis when a bloodless operative field is required. It has been claimed that using tepid lidocaine minimizes the burning sensation associated with its administration. The use of one part 7.5 percent bicarbonate with nine parts lidocaine for the same purpose has also been advocated.

Anesthetics are administered via a 30-gauge needle on a Luer-Lok syringe using either a proximal digital block or a distal digital block (wing block) procedure. Other techniques, such as median distal anesthesia or transthecal block, have not replaced the classic routes of anesthesia. Although emergencies related to minor surgery occur rarely, the ready availability of resuscitative equipment and expertise is essential.

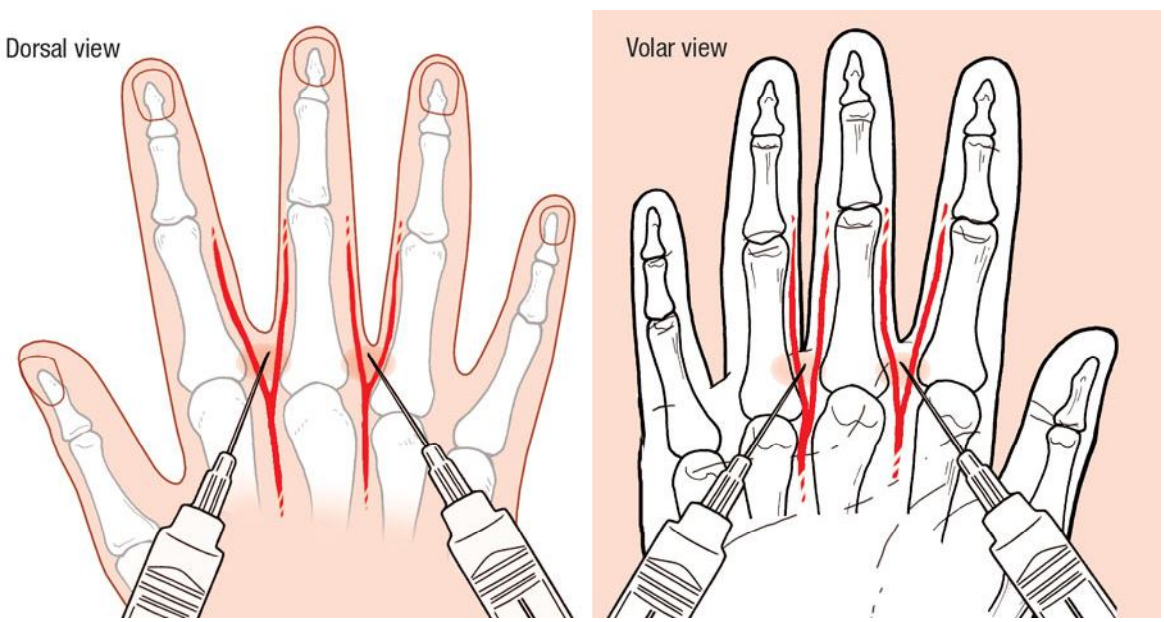
Proximal Digital Block

The proximal digital block procedure is less painful than the distal block procedure, but the anesthesia takes 5 to 10 minutes to become established. The hand is laid down flat, with the fingers spread, so that 1 to 2 mL of anesthetic can be administered by a dorsal injection, with a thin needle inserted and directed tangentially to the sides of the bony phalanx at the base of the involved finger and as far as the lateral side of the flexor tendon (Fig. 246-2). A tourniquet effect may inadvertently be produced by injecting more than 5 mL of anesthetic and should be avoided. The absence of blood reflux in the syringe should be verified before injection if a nondental syringe is used. When the operation is strictly localized to a lateral region, a block limited to the nerves ipsilateral to the lesion suffices, as in the case of a partial distolateral nail avulsion.

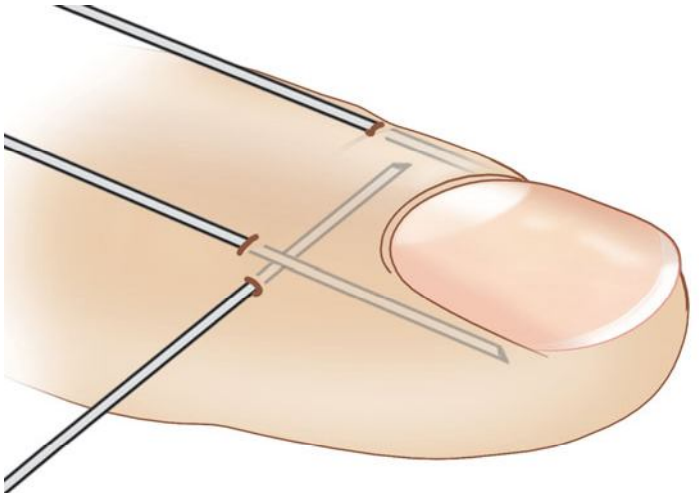
Distal Digital Block

The distal digital block procedure is more painful than the proximal block procedure, but anesthesia occurs immediately. This method is absolutely contraindicated, however, when bacterial infection in the region is being addressed. The latter requires wrist block or general anesthesia.

For a distal digital block, the needle is inserted just behind the junction of the proximal nail fold and a lateral nail fold and a few tenths of a milliliter of anesthetic is injected, which whitens the re-



▲ **FIGURE 246-2** Proximal digital block.



▲ **FIGURE 246-3** Distal digital block.

gion. The injection is continued by aiming the needle toward the pad. One then returns to the initial area to inject the proximal fold transversely. Finally, at the junction of the proximal fold with the lateral fold on the opposite side, one proceeds as described earlier (Fig. 246-3). The anesthesia is almost immediate, and when the procedure is done correctly, injections rarely have to be extended to the distal area of the finger.

Median distal administration is relatively simple and quick (Fig. 246-4). The needle is introduced at a 30-degree angle into the middle of the proximal nail fold and advanced distally into the underlying matrix. Anesthetic is injected slowly as the needle pierces first the nail plate, then the matrix, and finally the adjacent nail bed. The nail plate is soft and offers little resistance. Blanching confirms the delivery of anesthetic to the nail matrix and bed. Pain is brief and anesthesia nearly instantaneous. This method is suitable for most procedures performed on the proximal half of the nail unit. It is not suitable for matricectomy or complete nail avulsion.

▲ **FIGURE 246-4** Median distal block.

Transthecal Block

The flexor tendon sheath may be used as an avenue for introducing anesthetic to the core of the digit. Through centrifugal anesthetic diffusion all four digital nerves are anesthetized rapidly. This technique involves palmar percutaneous injection of 2 mL of lidocaine into the potential space of the flexor tendon sheath at the level of the palmar flexion crease using a 3-mL syringe and a 25-gauge hypodermic needle.

Wrist Block

TOURNIQUETS

DRESSING AND POSTOPERATIVE CARE

At the end of the operation, either the digit is cleansed with sterile 10 percent hydrogen peroxide solution and sprayed with a colorless disinfectant, or an antiseptic with hemolytic action is applied. The nail area is then covered with an antiseptic or antibiotic ointment on gauze or pads. Dressing must be done in a way that takes into account oozing, pain, and sensitivity. A bulky dressing provides a cushion against local trauma.

Dressings should be changed every other day or daily if there is infection. Several layers of sterile gauze should be kept in place by Micropore (2.5-cm) tape placed first on the dorsal aspect of the finger or toe, then on the ventral aspect, and last on the lateral edges in a U shape (a circular dressing should never be applied in the first week). Finally, use of an X-span tube dressing or Surgitube will give the patient more freedom to use the hand, but care must be taken that dressings do not constrict blood flow. During the first 48 hours the arm must be kept in a sling. Stitches are removed after 7 to 12 days.

When the feet are treated, daily chlorhexidine baths precede the care just described.

For all operations involving the toes, the patient should wear an appropriate shoe or sandal after the dressing has been applied. The patient should be recumbent for 24 to 48 hours, with the foot elevated to 30°.

POSTOPERATIVE COMPLICATIONS

Bleeding

Bleeding is seen after the tourniquet is removed but can be stopped by compressing the lateral edges of the distal interphalangeal joint. In cases of persistent bleeding, 35 percent aluminium chloride solution or a cellulose application (Gelfoam) should be applied.

Pain

Pain threshold varies from patient to patient. Postoperative pain can be almost non-existent if, in the absence of infection, the operation is followed by a periungual injection of 0.6 mL of 0.5 percent bupivacaine with 0.4 mL of 4 mg/mL dexamethasone. While the dressing is being put in place, the patient must be told what precautions to take. Providing a supply of moderately potent oral analgesics will help the patient to feel in control of any pain, even if the patient chooses not to take the tablets. Sometimes postoperative pain may be severe, and it is alleviated by elevating the extremity as much as possible for 2 days. Pulsating pain beginning after 36 to 48 hours may indicate an infection, which should be treated according to the results of bacterial culture of the organism. Any bulky dressing that is blood-stained after 24 hours should be changed.

Infection

Prophylactic antibiotic treatment is mandatory for patients with valvular

heart disease, including those with a prosthetic valve. Peripheral vascular disease and young age (in childhood the nail matrix is extremely fragile and behavior is less sanitary) are further indications. If there are ragged surfaces to the nail, which makes thorough preoperative cleaning difficult, antibiotics may prevent wound infection.

Postoperative infection may be caused by preoperative colonization or infection. Culture of preoperative swab specimens will indicate the best choice of drug after initial coverage with a broad-spectrum antibiotic.

Attention to detail is important. Carelessness may result in serious infectious complications in the soft tissue and occasionally in bone. Routine or preoperative nail cleansing softens the nail plate and keeps contamination to a minimum.

Misaligned Nail

Misaligned nail may result from a lateral longitudinal nail biopsy, especially if the routine 3-mm width is exceeded.

Relapse

Relapse will depend on the nature of the lesion treated. Warts, ingrown nails, and myxoid cysts can be difficult to eradicate.

Residual Dystrophy

Residual dystrophies are not unusual when surgery involves the proximal area of the matrix.

Unpredictable Complications

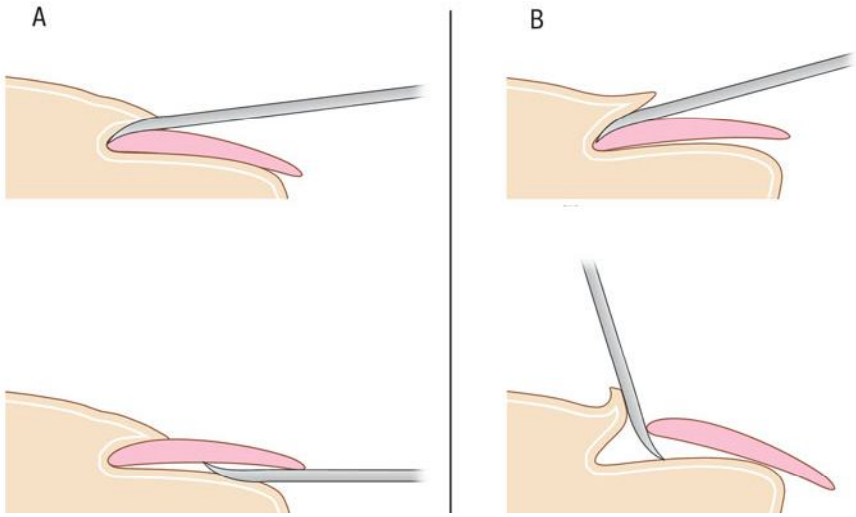
Implantation epidermoid cysts can occur in operation scars. Reflex sympathetic dystrophy after nail biopsy, although exceptional, has been reported.

NAIL AVULSION

The removal of the nail plate can be carried out using distal or proximal approaches. In both techniques, inserting the blunt instrument back and forth between the horny layer of the proximal nail fold and the nail plate loosens the proximal nail fold adherence.

Distal Approach

In the more commonly used distal approach, a Freer septum elevator or a dental spatula is inserted between the nail plate and nail bed (Fig. 246-5A). The nail is separated from its nail bed attachment using proximal force applied in anterior-posterior movements so as not to injure the longitudinal ridges of the nail bed. The detachment is completed by firmly pushing the instrument into the posterolateral corners of the nail plate. Then, one of the lateral edges is grasped with a sturdy hemostat, and extracted with an upward and circular movement to accomplish the removal of the nail plate.



▲ **FIGURE 246-5** **A.** Distal nail avulsion. **B.** Proximal nail avulsion.

Proximal Approach

The proximal approach for nail avulsion is advisable when the subungual distal area adheres strongly to the nail plate and when the hyponychium may be injured by the subungual introduction of the spatula. The proximal nail fold is freed as described in Distal Approach. The spatula is then used to reflect the proximal nail fold, and is delicately inserted under the base of the nail plate where adherence is normally weak (see Fig. 246-5B). The instrument is advanced distally following the natural cleavage plane, and this operation is repeated on the entire width of the subungual region. After the last attachments are freed, the nail plate is easily pulled out.

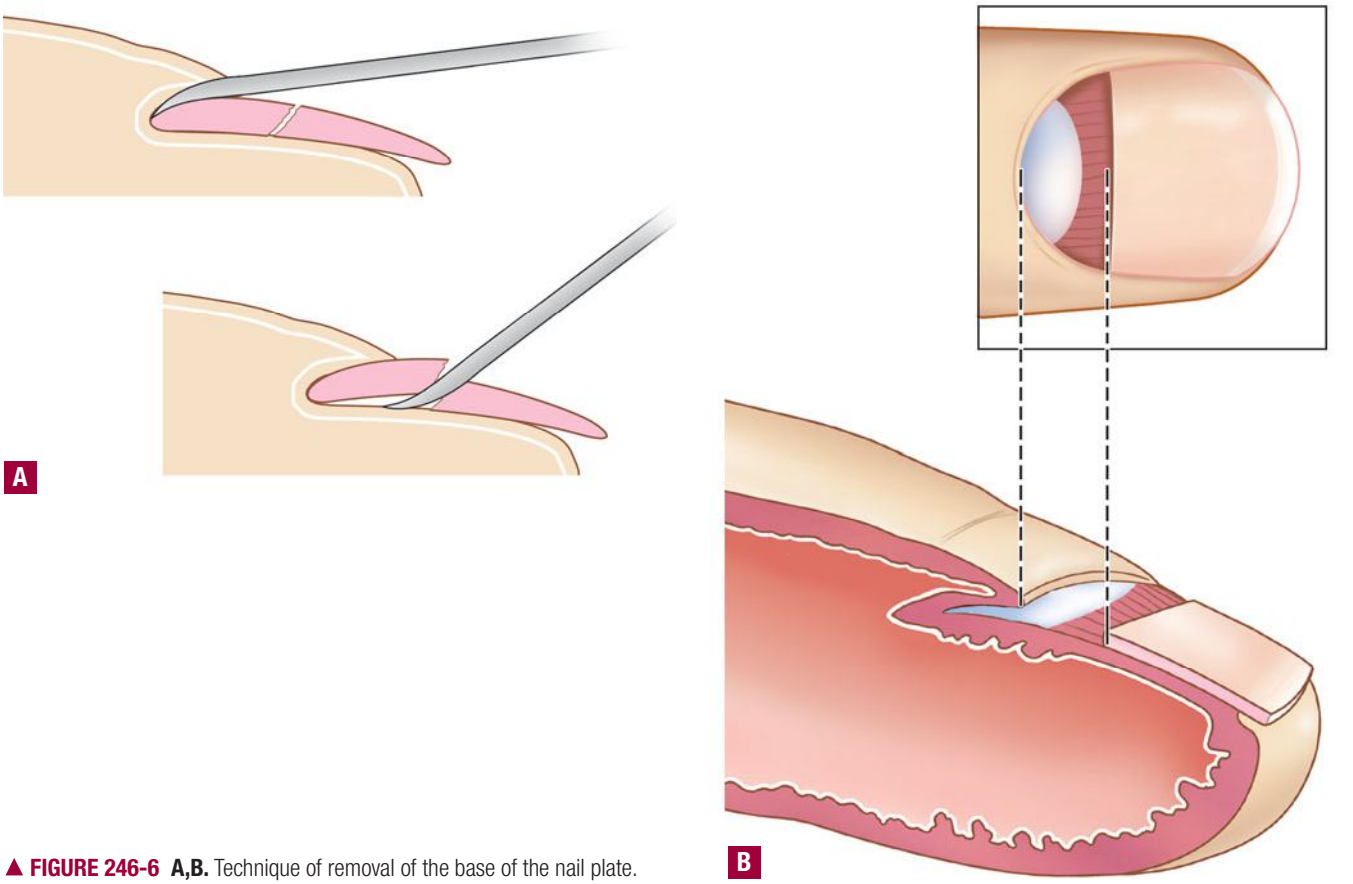
Total surgical removal should be discouraged, however, because the distal nail bed may shrink and become dislocated dorsally. In addition, the loss of counterpressure produced by the removal of the nail plate allows expansion of the distal soft tissue, and the distal edge of the re-growing nail then embeds itself. In patients at high risk, non-surgical removal of the nail plate should be considered when necessary. This can be accomplished by applying 40 percent urea paste directly to the nail after protecting the surrounding skin. Urea acts on the bond between nail keratin and diseased nail plate, sparing only the normal nail tissue.

Partial Nail Avulsion

The problems that can arise after total nail avulsion may be overcome by partially avulsing the nail. Partial distal avulsion requires only separation of the nail from the distal nail bed. This procedure can be performed under local anesthesia in selected patients, when, for instance, a fungal infection is of limited extent. An affected portion of the nail plate may be removed in one session, even when the disease has reached the deeper regions of the subungual tissue beneath the proximal nail fold. Commonly, an English anvil nail splitter or a double-action bone rongeur is used for this procedure.

Partial surgical section of the lateral and/or medial segment of the nail plate may be sufficient for the treatment of distal lateral subungual onychomycosis. In the toe, this procedure leaves enough normal nail to counteract the upward forces exerted on the distal soft tissue when walking, and this will prevent the appearance of a distal nail wall.

In proximal subungual onychomycosis, removal of the non-adherent base of the nail plate, cut transversely, leaves the distal portion of the nail in place (Fig. 246-6), which decreases discomfort. Similarly, an acute paronychia that



▲ **FIGURE 246-6** **A,B.** Technique of removal of the base of the nail plate.

does not respond to appropriate antibiotics within 48 hours should be treated surgically by removing the base of the nail plate.

SURGICAL APPROACHES TO THE DIFFERENT TISSUES OF THE NAIL APPARATUS

Nail Matrix

When surgery involves the nail matrix, there are three primary approaches, including (1) a reduction in its width or (2) its length for removal of tumors, for instance, by using a cold steel procedure or (3) a 2- to 3-mm punch biopsy. In contrast to these three procedures, complete matricectomy, that is, ablation of the nail-forming tissue, is rarely performed because the nail is then permanently lost.

After reduction of the nail matrix width, one is left with a narrower nail and after reduction of the length, with a diminution in the thickness of the nail. Reduction of the matrix width is a useful and/or necessary procedure in the following major circumstances:

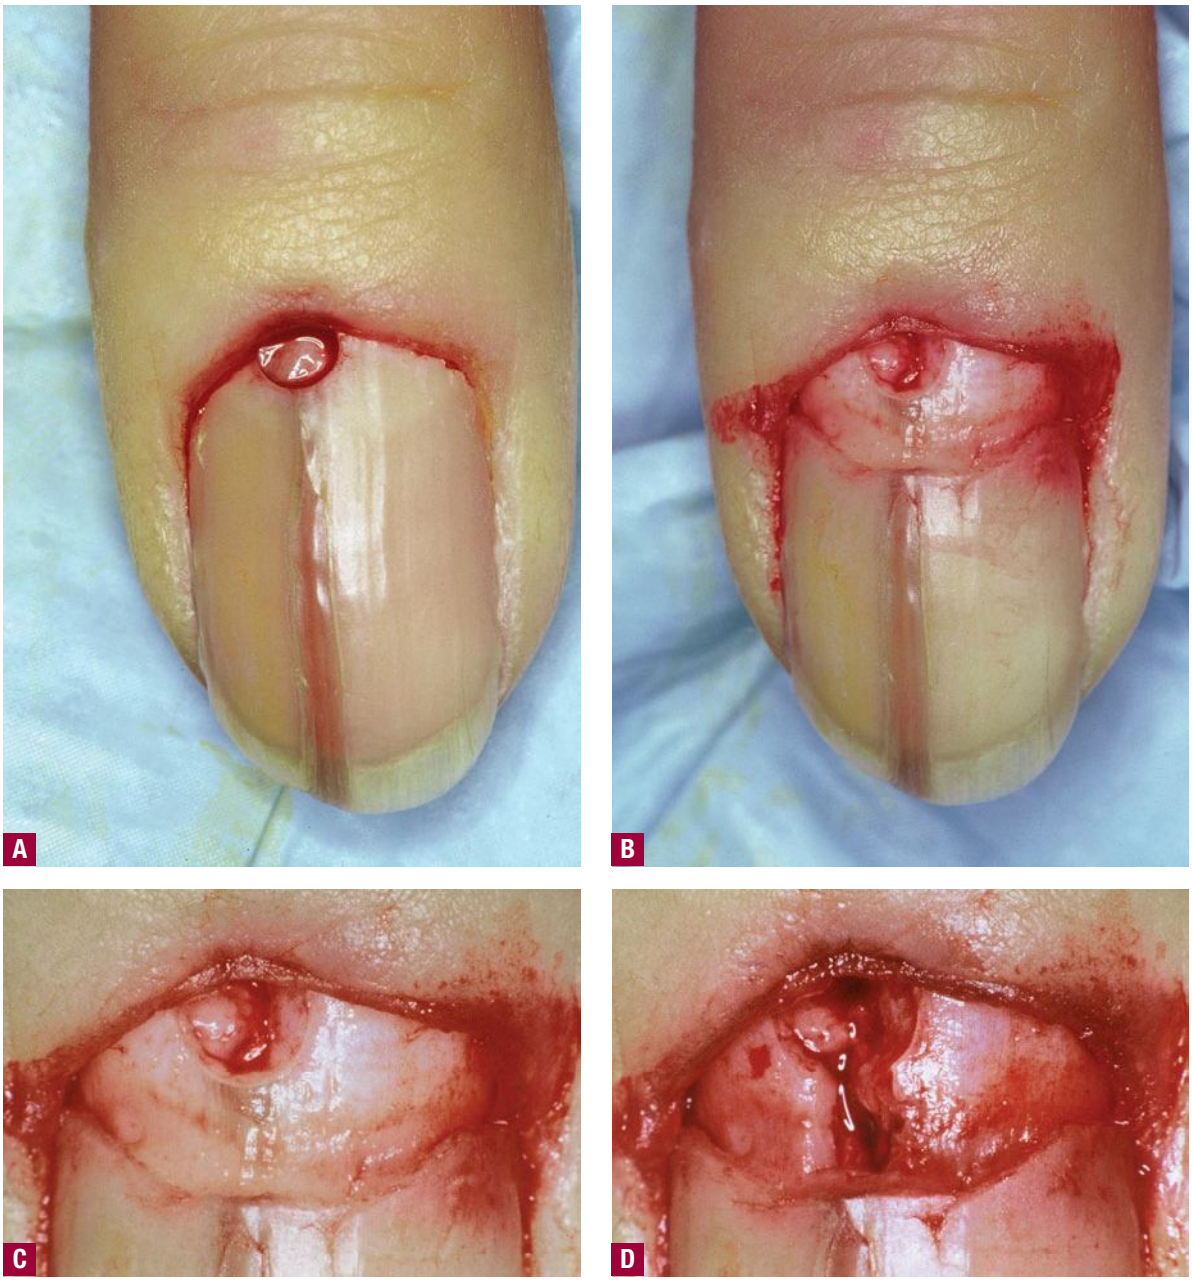
- Need for lateral-longitudinal biopsy
- Lateral nail splitting
- Benign or malignant tumor in the lateral third of the nail apparatus
- Longitudinal melanonychia in a lateral location
- Ingrown nail
- Racquet nail

Reduction of the matrix length is necessary only in limited cases: to obtain a transverse elliptical biopsy specimen, to treat tumors that are 3 mm wide or larger, and to thin thick nails in patients with dystrophic congenital and/or hereditary disorders.[2]

BIOPSY[3–5] Biopsy of the nail matrix is performed to determine the histopathologic features of a lesion or to clarify an uncertain clinical diagnosis.

A 3-mm punch biopsy may be performed through the nail plate into the matrix. Three millimeters is the maximum size that does not produce serious dystrophy, although even biopsies of this size can cause such effects if carried out in the most proximal portion of the nail matrix. When a punch biopsy is used to sample longitudinal melanonychia of less than 3 mm in width, the circumferential incision is made around the origin of the band, through the nail plate (Fig. 246-7A). This area may be distal enough to be reached by pushing back the cuticle (Fig. 246-7B), but if it is more proximal, the proximal nail fold may have to be reflected using a posterolateral incision. The next step is to remove the proximal third of the nail plate (see Fig. 246-7B and C), while leaving the cylinder of tissue containing the origin of the longitudinal melanonychia still in place. This technique allows the surgeon to inspect the surrounding nail matrix and bed with a magnifying lens to determine whether pigment extends around the punch incision (see Fig. 246-7C and D) and facilitates the removal of the cylinder of biopsy tissue with a Gradle scissors.

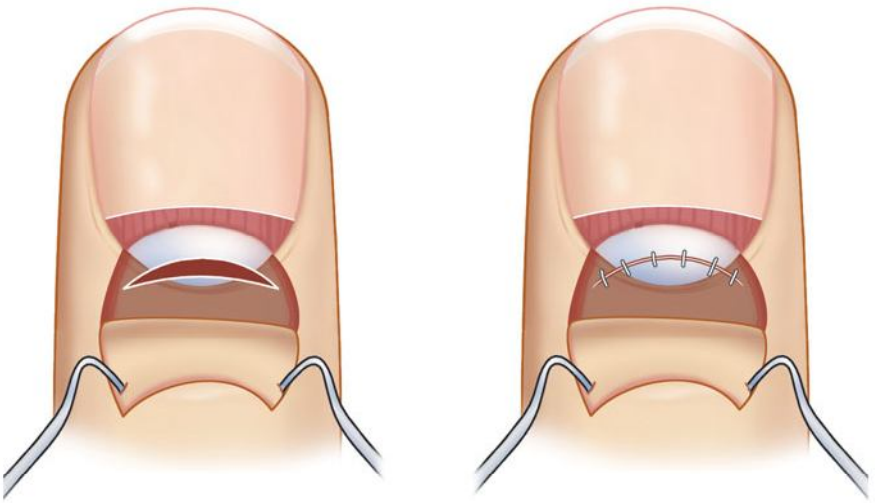
For lateral longitudinal biopsy (Fig. 246-8), an elliptical incision may be made on either side of the nail plate and proximal nail fold. For the most part, the incisions parallel the lateral edge of the nail plate. Beginning in the lateral nail groove, the incisions should include a 3- to 4-mm nail segment reaching to the bone. This ensures that a full-thickness fragment of the matrix with its lateral horn is obtained. Slightly curved iris scissors are useful for separating the tissue from the bone. Starting at the tip of the digit, one proceeds proximally while maintaining contact with the bony phalanx. Lateral longitudinal biopsy is the advised procedure when longitudinal melanonychia[3] is located in the lateral part of the nail plate.



▲ **FIGURE 246-7** **A.** Punch biopsy of longitudinal melanonychia of less 3 mm in width. **B–D.** Removal of the base of the nail plate (**B**) to allow easy removal of the biopsied cylinder of matrix tissue (**C**) and pigment left distally (**D**).

▲ **FIGURE 246-8** Lateral longitudinal biopsy of longitudinal melanonychia located within the lateral third of the nail plate.

For transverse biopsy (Fig. 246-9), two small oblique incisions are made on each side of the proximal nail fold. The fold is then reflected to expose the matrix area. The proximal third of the nail plate is avulsed. Then, the lesion is removed by excising an elliptical or crescent-shaped wedge of tissue with the convex portion of the crescent paralleling the anterior border of the lunula. When longitudinal melanonychia lies within the midportion of the nail plate, the potential for postoperative dystrophy is great, and selection of the optimal biopsy method is difficult. It is important to establish the matrix origin (proximal or distal) of longitudinal mel-



▲ **FIGURE 246-9** Transverse biopsy of the nail matrix.

anonychia preoperatively, because the more proximal the origin, the greater the risk of nail dystrophy.[3] The origin of pigmentation may be determined by microscopic examination of Fontana-Masson–stained clippings from the free edge of the nail.

RACQUET NAIL

SPLIT-NAIL DEFORMITY[6] The common causes of split-nail deformity include trauma, surgery, lichen planus, and tumors. Split-nail deformity may occur in either the lateral or the medial region. The appropriate surgical technique varies accordingly.

If the split is located within the lateral third of either portion of the nail, especially when it is close to the lateral margin, the best method is the technique recommended for lateral longitudinal nail biopsy—that is, the removal of the lateral portion of the nail with the defect. If the split is located in the middle region of the nail and involves its whole length, the proximal nail fold is carefully freed from the underlying nail plate, obliquely incised at both sides, and reflected to expose the whole matrix area (Fig. 246-10). The nail plate bordering the split is cautiously cut as a rectangular block approximately 1 mm wider than the scar that has to be excised. The nail bed and matrix of the defective tissue are dissected from the bone to allow an exact approximation of the remaining bed and matrix, which are sutured with 6-0 monofilament resorbable sutures. To prevent the sutures from tearing the tissue, 3-0 sutures are put through the nail plate. When these threads are knotted firmly, the matrix and nail bed are further approximated, which relaxes the 6-0 sutures.

If the scar is too wide to allow primary closure of the defect, relaxing longitudinal incisions along the lateral nail grooves down to the bone usually permit suturing. An alternative approach is the formation of a Schernberg nail bed–matrix flap with an L-shaped incision of the lateral aspect of the finger.

NAIL ABLATION AND ISOLATED MATRICECTOMY Nail ablation (Fig. 246-11) is the definitive removal of the entire nail organ and matricectomy, the complete extirpation of the nail matrix, which results in permanent nail loss. The principle of nail ablation is the complete removal of the nail unit with hyponychium, nail bed, matrix, and lateral and proximal nail folds. Except for treatment of malignant tumors of the nail apparatus, nail ablation is rarely indicated. It may be necessary in the case of an excessively painful nail treated several times without success, but this should be an exception. Scalpel excision is strongly advocated whenever the surgical specimen needs histopathologic examination. If periungual pigmentation is associated with longitudinal melanonychia or if the latter is wider than 6 mm or the full thickness of the nail is pigmented, a large portion of the matrix would necessarily be involved. Under these circumstances, the underlying disease process in unlikely to be benign. The entire portion of the involved nail apparatus has to be excised en bloc.

The defect from nail ablation (see Fig. 246-11B) may be covered with a free graft (split-thickness, full-thickness, reversed dermal graft), which usually takes on the bone in this particular location. A cross-finger flap is a very useful alternative to a free graft. The use of the skin from the intermediate phalanx of a neighboring finger is more convenient for the patient than skin from the thenar area of the palm.

If only permanent nail matrix removal is necessary, the procedure is less extensive.

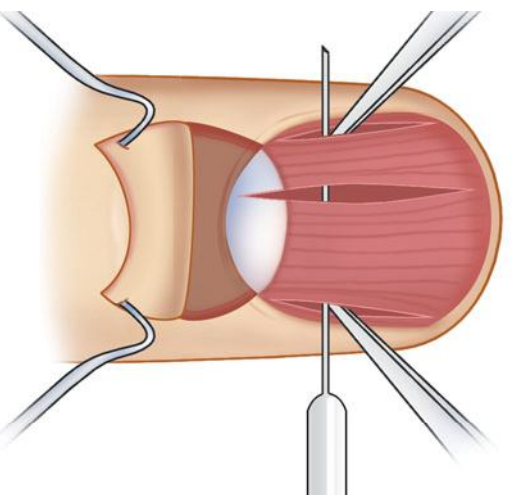
In cases in which pathologic examination of the removed tissue is unnecessary, phenol cautery, rather than scalpel excision, is the preferred technique for matricectomy. Most patients return to normal ambulation and activity as early as 1 day after the operation.

Nail Bed

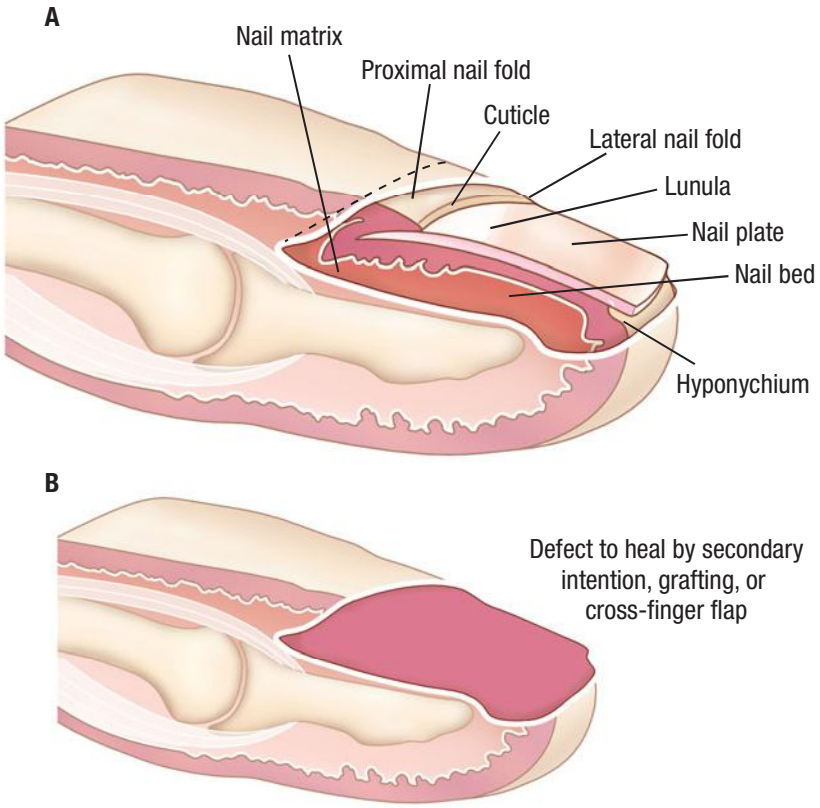
Nail bed surgery is performed for biopsy, removal of tumors, and treatment of nail dystrophies such as onychogryphosis.

BIOPSY Biopsy (Fig. 246-12) may be useful in any pathologic condition involving the nail bed.

Punch biopsy is done with a 3- or 4-mm diameter punch, which is driven perpendicularly into the nail plate in a circular motion down to the bone. How-



◀ **FIGURE 246-10** Treatment of split nail in the middle region of the nail plate.



▲ **FIGURE 246-11** Nail ablation. **A.** Area of excision. **B.** Remaining defect.

ever, it is not always easy to extract the cylinder cut with an area this small. One useful technique is to perforate the nail plate with a 6-mm punch without injuring the underlying tissue (see Fig. 246-12A). The covering nail is then detached by using the tip of the scalpel to remove the disk of nail, and the biopsy is performed easily by using the 4-mm punch to the bone. The tissue can then be released from its tether with fine scissors. It is advisable to replace the 6-mm disk of nail keratin, after cleaning with 10 percent hydrogen peroxide, to cover the hole. If the nail plate is thick, rotating grinders can be used to thin it down and facilitate the transungual biopsy.

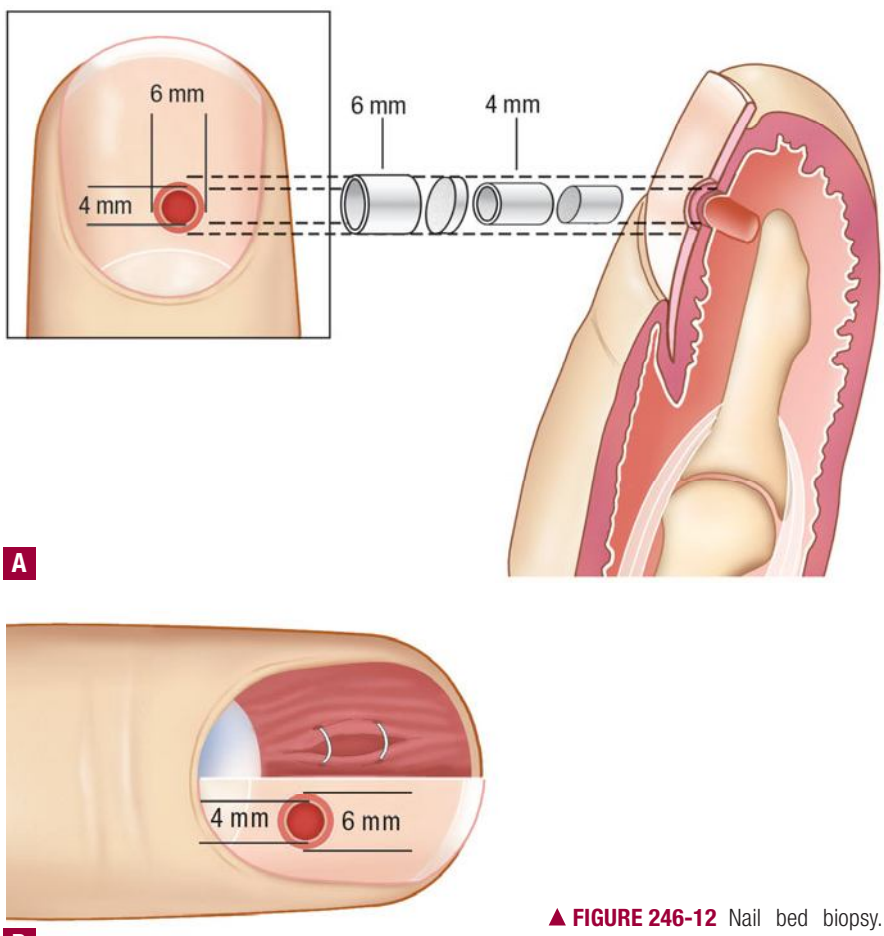
If a larger nail bed fragment is needed, fusiform biopsy with a major longitudinal axis can be performed after partial avulsion of the lateral half of the nail (see Fig. 246-12B) or after total avulsion if the fragment is central. After excision, the nail bed is undermined to facilitate reapproximation of both sides. The suture needle is used generously on these fragile subungual tissues. The wound is stitched with 6-0 resorbable thread. It is sometimes useful to make relaxing incisions at the most lateral margins of the nail bed.

SUBUNGUAL HEMATOMA In cases of subungual hematoma, acute trauma with severe pain is always remembered by the patient. Depending on the site and intensity of the injury, the hematoma may be visible almost immediately or it may grow out from under the proximal nail fold within a few weeks.

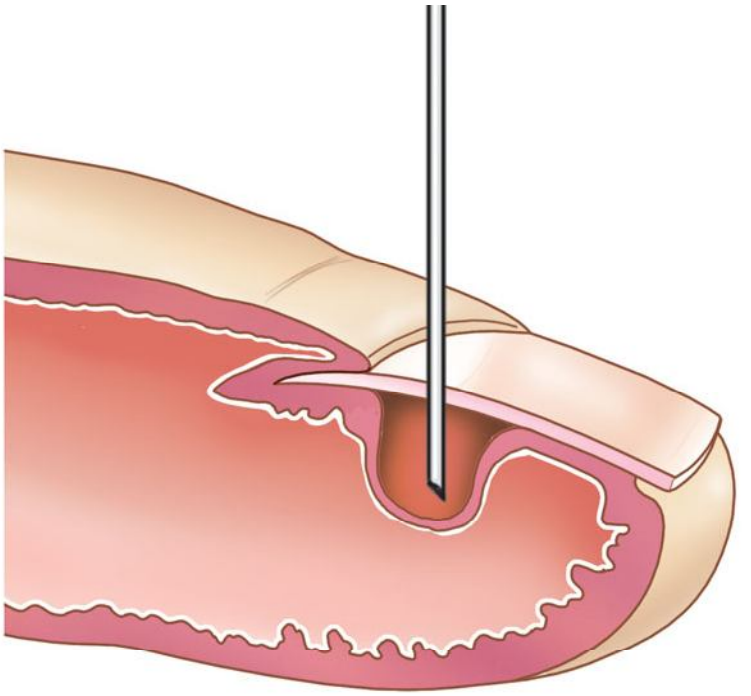
When the hematoma is partial (less than 25 percent of the visible portion of the nail), it should be drained with a pointed scalpel or by hot paperclip cautery over the center of the dark spot (Fig. 246-13). This will produce relief from pain. Sometimes the nail sloughs as the new nail regenerates beneath the old one.

Small hematomas may be included in the nail, but they cannot be degraded to hemosiderin and results of the Prussian blue test will be negative. Therefore, to demonstrate the nature of the blackish pigment, scrapings are boiled in a small test tube with Hemostix, which gives a positive benzidine result.

A hematoma involving more than 25 percent of the visible portion of the nail is a sign of significant nail bed injury. A radiograph is mandatory, because the phalanx may be fractured. The nail plate is carefully removed and the hematoma



▲ **FIGURE 246-12** Nail bed biopsy. **A.** Punch biopsy. **B.** Fusiform biopsy.



▲ **FIGURE 246-13** Treatment of partial hematoma.

evacuated. Traumatic nail bed laceration or wounds need a surgical approach to avoid delayed complications.

Nail bed lacerations can be sutured after thorough cleaning with antiseptics, using 6-0 resorbable monofilament material. The avulsed nail plate should be put back to cover the wound and then kept in place by suturing to the lateral nail folds or the fingertip.

Nail bed defects larger than 4 mm can be repaired using a split-thickness graft taken either from the nail bed of the same digit or from the nail bed of a great toe.

The torn nail bed should be sutured with 6-0 resorbable thread, and large bites of tissue should be taken so that the suture material does not pull through when it is tied. The nail plate is cleaned, shortened, and slightly narrowed, and then replaced with sutures into the lateral nail folds. The stitches are left in for 2 weeks.

Chronic hematomas are usually painless and are caused mainly by repeated microtrauma from either ill-fitting footwear or sporting activities. A notch is made with a scalpel blade at the distal and proximal border of the pigmented area. Observation over a 3-week period will demonstrate whether the nail grows independently of the pigmentation or with it. However, chronic hematoma may resemble subungual melanoma and pose a distressing problem, and nonmigrating hematoma should be ruled out.

Proximal Nail Fold

BIOPSY A 2- to 3-mm punch may be used for biopsy of a tumor. A blister may be completely removed by shave biopsy using half a razor blade (see eFig. 246-13.1 in on-line edition). Excision of a 3-mm crescent-shaped tissue segment in the proximal region of the lateral nail folds may be helpful in the evaluation of collagen disease.

RECALCITRANT CHRONIC PARONYCHIA Presence of a foreign body (e.g., hair) under the proximal nail fold is the main cause of recalcitrant chronic paronychia. The disorder manifests as a red swelling that is painless except when pressed, with secondary retraction of the paronychial tissue whose cuticle has disappeared and with recurrent episodes of acute paronychial inflammation.

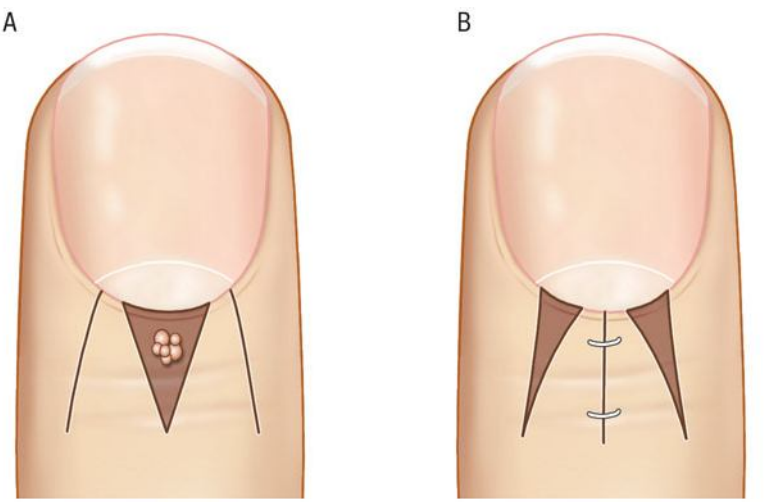
For crescentic excision, a Freer septum elevator is inserted under the proximal nail fold to protect the matrix and extensor tendon. A No. 15 Bard-Parker blade is used to excise, en bloc, a crescent-shaped full-thickness skin segment, 4 mm at its greatest width, that extends from one lateral nail fold to the other. Use of a beveled incision prevents accidental damage to the proximal nail matrix and the most proximal portion of the proximal nail fold, which is responsible for the normal shine of the nail plate (see eFig. 246-13.2 in on-line edition).

In patients who experience repeated acute flares associated with chronic paronychia, additional removal of the base of the nail is useful.

TUMORS OF THE PROXIMAL NAIL FOLD Different techniques can be used to treat tumors of the proximal nail fold, depending on the nature of the tumor, its location, and the length of its long axis.

Crescentic excision is useful for small distal tumors. The crescent should not exceed 4 mm at its greatest width.

Tumors of the proximal nail fold that are situated in a median position and have a longitudinal axis longer than 4 to 5 mm can be excised with a wedge of proximal nail fold whose base is located at the free margin and whose apex points proximally (Fig. 246-14A). Two relaxing lateral incisions are then made in the proximal nail fold to allow suturing of the wedge-shaped defect after the



▲ **FIGURE 246-14** **A.** Tumor of the proximal nail fold situated in a median position. **B.** Suturing of the defect after relaxing lateral incisions are made and the proximal nail fold has been released from the nail plate.

undersurface of the proximal nail fold has been released from the nail plate (see Fig. 246-14B).

The resulting symmetric narrow defects on both sides heal rapidly by secondary intention.

A small tumor on the lateral part of the proximal nail fold may be treated using a wedge-shaped excision (see eFig. 246-14.1 in on-line edition). Only one lateral relaxing incision is made at the opposite region of the proximal nail fold. To obtain better healing of the secondary defect, which is wider than in the procedure using two relaxing incisions, the surgery may be supplemented by making a relaxing crescent-shaped incision in the proximal nail fold.

A dorsal flap can be raised from the proximal nail fold by using two dorsolateral incisions and a horizontal one proximal to the cuticle. This gives complete exposure of subcutaneous tumors.

RECONSTRUCTION OF THE PROXIMAL NAIL FOLD Reconstruction of the proximal nail fold may be necessary after any injury (accident, burn, avulsion caused by rapidly rotating belts and sanders, etc.). If the irregular tissue is excised, it is sometimes possible to re-create the distal curve of the proximal nail fold, which may produce a nearly perfect restoration. The proximal nail fold may also be restored by using two long, narrow, V-shaped transposition flaps from the lateral aspects of the terminal phalanx.

Lateral Nail Fold

A 2- to 4-mm punch can remove a tumor of the lateral nail fold (see eFig. 246-14.2 in on-line edition). Benign tumors may be removed by taking an elliptical wedge of tissue from the lateral nail fold and lateral nail wall. Malignant tumors, such as in Bowen disease, are treated by excision of the whole lateral nail fold or by Mohs micrographic surgery followed by healing by second intention.

INGROWN NAILS Ingrown nail is a condition that occurs mainly in the great toe. It is created by impingement of the nail plate into the dermal tissue distally or into the distolateral nail groove. Irrespective of the initial cause, the condition finally presents with a nail bed that is too narrow for its nail plate. Logical treatment is therefore aimed at correcting this disparity.

Distal Toenail Embedding. Surgical avulsion or the loss of the toenail from trauma, such as tennis toe, may initiate the pathology. The distal subungual tissues released from the physiologic counterpressure of the nail plate become hypertrophic, and the newly formed nail plate abuts this distal wall. To treat the condition, a crescentic wedge-shaped excision is made around the distal phalanx (see eFig. 246-14.3 in on-line edition). The wedge should be 4 mm at its greatest width and must be dissected from the bone. The defect is closed with 5-0 monofilament sutures, which should be removed after 12 to 14 days.

Juvenile (Subcutaneous) Ingrown Nails. Juvenile or subcutaneous embedded nail is the most common type of ingrown nail. The nail is usually embedded medially, but both sides are often affected. In an effort to relieve the pain, the patient often tries to cut off the offending corner under the inflamed and swollen soft tissue. The remaining portion gives rise to a nail spicule piercing the epithelium of the lateral nail groove, which produces secondary infection and excessive granulation tissue.

Treatment at the early stage must be conservative but demands a high degree of patient compliance. The foot is soaked in warm water with povidone-iodine soap; then, under local anesthesia, the nail spicule is removed and a wisp of cotton wool is placed between the nail and the lateral nail groove. It should be moistened repeatedly with a disinfectant.

For definitive cure, surgical excision or, better, chemical suppression of the lateral horn of the nail matrix permanently narrows the nail. The lateral fifth of the nail plate is freed with a nail elevator from the proximal nail fold and the subungual tissues. It is then cut longitudinally with an English nail splitter or nail-splitting scissors and extracted using a sturdy hemostat. The lateral matrix horn is cauterized with a freshly made solution of liquefied phenol (88 percent solution) (see eFig. 246-14.4 in on-line edition). Above all, a bloodless field is needed, because blood inactivates phenol. Hemostasis is therefore accomplished with a tourniquet, and the blood is carefully cleaned from the space under the proximal nail fold using sterile gauze. The surrounding skin is protected with petroleum jelly. The phenol is rubbed onto the matrix epithelium for 3 minutes with a cotton-tipped swab that is changed two or three times. Postoperative pain is minimal because phenol has a local anesthetic action and is antiseptic. The matrix epithelium is sloughed off, and oozing is usual for 2 to 6 weeks. Daily warm foot baths with povidone-iodine soap accelerate healing.

Pincer Nail[7]. Overcurvature of the nails may affect the great toe alone or all the digits. This condition may be so painful that even contact with a bedsheet becomes unbearable.

When the condition is mild, the nail brace technique is used, which aims at correcting the inward distortion of the nail by maintaining continuous tension on the nail plate. A stainless steel wire brace is fitted to the nail plate. A series of adjustments adapted to the gradual decrease of curvature is made over a period of 6 months and results in a painless correction of the pincer nail. Because the underlying bone pathology remains untreated, however, relapse is usual. Therefore, the definitive cure—the use of phenol cautery on the lateral matrix horns—is undoubtedly the simplest effective treatment modality.

Hypertrophy of the Lateral Nail Fold. Hypertrophic lateral nail folds are usually the result of long-standing ingrown nails. Inflammation may range from the sub-clinical to the severe. For treatment, approximately one-fifth of the nail digging into the lateral nail fold is removed. Then an elliptical wedge of tissue is taken from the lateral nail wall of the toe, down to the bone (see eFig. 246-14.5 in on-line edition). Suturing of the defect pulls the lateral nail fold away from the offending lateral nail edge. In severe cases, this procedure may be combined with phenol cautery of the lateral horn of the matrix. In contrast to adult-acquired hypertrophy of the lateral nail fold, congenital lateral hypertrophic lips disappear progressively and spontaneously within 12 months.

Congenital Malalignment of the Great Toenail[8]. In congenital malalignment of the nail of the great toe, typically the nail is malaligned laterally, with transverse furrows on a thick brownish or greenish nail. In 50 percent of cases this condition corrects itself without therapy before the age of 10. If the appearance is extreme, surgery diminishes the risk of permanent dystrophy.

Treatment requires rotation of a bulky nail unit flap, including the entire nail, nail bed, and matrix (see eFig. 246-14.6 in on-line edition). This demands creation of an external Burow's triangle. An eccentric crescent-shaped excision is made

to undermine the nail unit, with the maximum width located on the internal side of the foot, corresponding to the side to which the nail needs to be redirected. This crescent ends on each side 3 to 4 mm behind the most proximal part of the proximal nail fold. The nail bed and the matrix are then undermined and lifted until the fibers of the extensor tendon are visible on its bony insertion, and the dorsal expansion of the lateral ligament of the distal interphalangeal joint is cut.

Suturing the edges of the excised triangle together reduces the loss of cutaneous substance. The nail unit is rotated inwardly, because the maximum cutaneous resection is mostly distal and medial.

CHAPTER 247

Cryosurgery and Electrosurgery

Justin J. Vujevich
Leonard H. Goldberg

HISTORY

CRYOGENS

Liquid nitrogen is the cryogen of choice in dermatology. It is easy to store and use, environmentally friendly, nonflammable, inexpensive, and at –195.8°C (–320.4°F), has the lowest temperature of all the common cryogens, causing rapid freeze of treated tissue.

Other available cryogens include fluorinated hydrocarbons, solid carbon dioxide, and nitrous oxide (Table 247-1). Fluorinated hydrocarbons are used as topical sprays to provide temporary anesthesia before the removal of skin lesions and the administration of vaccinations. Cryogen spray cooling is also used to reduce the pain of laser surgery and eliminate overheating of the epidermis.[4]

CRYOBIOLOGY

Cryobiology refers to the study of the effects of subzero temperature on living systems. Tissue destruction from cryotherapy results from direct cell injury, vascular stasis, and the local inflammatory response.

Freezing cells convert water to ice (crystallization). Rapid freezing causes intracellular ice crystal formation with the disruption of electrolytes and pH changes, whereas slow freezing causes extracellular ice formation and less cell damage. Therefore, tissue effects and cell death are most readily achieved when tissue is frozen rapidly.[5]

During thawing, re-crystallization occurs when ice crystals fuse to form large crystals that disrupt cell membranes. As the ice melts further, the extracellular environment becomes hypotonic, causing water to infuse into cells and cause cell lysis.[6] The longer the thawing time, the greater damage to the cells because of increased solute effect and greater re-crystalization.[6]

After freezing, stasis within the vasculature occurs. This loss of circulation and resultant anoxia is a major mechanism of injury from cryosurgery. As the tissue thaws over 0°C (32°F), a brief hyperemic response ensues, with resultant edema and inflammation.

TARGETS OF CRYOTHERAPY

Table 247-2 lists targets of cryosurgery with associated cell death temperatures. Melanocytes are the most sensitive to cryosurgery, with cell destruction at –4°C to –7°C (24.8°F to 19.4°F).[8] As a result, depigmentation may occur, especially in darkly pigmented individuals. Keratinocytes require longer freezing to –20 to –30 °C until cell death and are more resistant to cooling effects. Fibroblasts are the most resistant to freezing and do not undergo cell death until –30°C to –35°C (–22°F to –31°F). A temperature of –50°C to –60°C (–58°F to –76°F) is needed for destruction of malignant lesions, whereas lesser degrees of freezing are needed for benign lesions.

TABLE 247-1
Cryogens Used in Cryosurgery

AGENT	BOILING POINT (°C/°F)
Freon	–40.8/–41.4
Solid CO_2	–79.0/–110.2
Nitrous oxide	–89.5/–129.1
Liquid nitrogen	–195.8/–320.4

PATIENT SELECTION AND CONSIDERATIONS FOR CRYOSURGERY

Several factors, including lesion type, size, depth, border, location, and patient skin type, should be considered when cryosurgery is a treatment choice. Absolute contraindications to cryosurgery include lesions that require histopathology for diagnosis and recurrent non-melanoma skin cancers. Relative contraindications to cryosurgery include patients with cold urticaria, abnormal cold intolerance, cryoglobulinemia or cryofibrinogenemia, or tumors with indistinct borders or darkly pigmented features.

Precautions should be undertaken when treating lesions overlying nerves, such as the postauricular nerve on the neck or digital nerves on medial and lateral fingers and toes. Damage may result in regional paresthesia or motor dysfunction. Cryosurgery may not be indicated when treating sites prone to scarring with retraction, such as the eyelids, mucosa, nasal ala, and auditory canal. Finally, patients with darkly pigmented skin may have hypopigmentation at treated sites.

TABLE 247-2
Tissue Target Cell Death Temperatures

CELL	TEMPERATURE (°C/°F)
Melanocytes	–4 to –7 (24.8 to 19.4)

Fibroblasts	–30 to –35 (–22 to –31)

▲ **FIGURE 247-1** CRY-AC® cryosurgical unit (Brymill Corporation).

TECHNIQUES AND EQUIPMENT FOR CRYOSURGERY

There are several cryosurgical techniques that can be used in treating skin lesions. The open spray method is most frequently used. This method uses a hand-held cryosurgical unit with fingertip trigger (Fig. 247-1). Spray tips with varying-sized apertures are attached to the unit, emitting a stream of liquid nitrogen toward the lesion from a distance of 1 to 2 cm.

Although freeze times vary for lesion types, an intermittent spray in a solid, circular, or paintbrush pattern is normally used. Longer spray times are required for thicker, keratotic lesions or malignant lesions; shorter times are required for thinner, atrophic, or benign lesions. The intermittent spray helps to localize treatment to the lesion with a small freeze halo, thus minimizing collateral normal tissue damage. This is particularly important when treating lesions around the orbital, nasal, auricular, genital, or periungual regions.

As the lesion is treated a lateral freeze spreads beyond the margins of the lesion. The measurement of the surface radius of the freeze is equal to the central depth of the freeze into the skin.[6] Temperature gradients exist within the freeze, with colder temperatures in the middle and warmer temperatures toward the periphery. In general, superficial lesions should have a clinical freeze margin of 2 to 3 mm, and malignant or deeper lesions should have a clinical freeze margin of 5 mm to ensure successful treatment.

The closed technique uses a copper cryoprobe that is attached to the cryosurgical unit. Once the metal probe is pressed against a lesion on the skin, the trigger of the unit is squeezed, and liquid nitrogen leaves the unit through a conduit line that maintains it in a closed system. This technique is useful for treating small, well-circumscribed lesions or lesions found in confined locations.

Similarly, a metal, cone-sized chamber can be attached to the cryosurgical unit and held in contact with the lesion. This allows liquid nitrogen spray to enter the cone and rapidly freeze the lesion. Another cone-apparatus option includes holding an otoscope cover tip against the lesion with one hand while freezing with the cryosurgical unit in the other hand. Treatment times using the cone method should be decreased because the final temperature at the orifice of the cone is obtained faster, when compared with an open spray.

If a cryospray unit is not available, the dipstick technique can be used. First, a small amount of liquid nitrogen is poured into a polystyrene cup or other insulated container. Cotton-tipped swabs are placed tip-down in the container and cooled. Using firm pressure, the cotton-tips are placed against the lesion until a 2- to 3-mm halo forms around the treated lesion. This method treats lesions on the body where surrounding tissue must be spared, such as periorbital, mucosal, nail, and genital regions.

Alternatively, tissue forceps can be placed in the container and allowed to cool. This method is useful for treating filiform lesions such as verrucae and skin tags. The metal forceps cool rapidly, so insulated gloves should be worn while holding the forceps to prevent freeze injury to the practitioner's fingers.

CRYOTHERAPY FOR BENIGN AND PRE-MALIGNANT SKIN LESIONS

There are many benign lesions that can be treated with cryosurgery. Several lesions commonly treated with liquid nitrogen are presented below.

Seborrheic Keratosis

The spray technique is an effective modality for treating this common lesion. Although longer freeze times of 10 to 15 seconds with a 1- to 2-mm halo are required for these raised growths, too aggressive freezing may result in scarring or hyperpigmentation. For cosmetic purposes and to prevent pigmentation changes, a lighter freeze followed by curettage may be preferential. Forewarn patients that a second treatment may be required, especially for thicker seborrheic keratoses.

Solar Lentigo

As previously described under Targets of Cryotherapy, pigmented cells are highly susceptible to freezing. Therefore, these lesions require a shorter freeze time of 3 to 5 seconds with minimal halo. For darker-skinned individuals, care must be taken not to induce hypopigmentation at treatment sites. Therefore, a test site in a cosmetically less noticeable region may be performed first before treating multiple lesions on sun-exposed areas. In addition, sunscreen with ultraviolet A and ultraviolet B protection should be advocated pre- and post-treatment.

Keloids and Hypertrophic Scars

Treatment of keloids and hypertrophic scars is frequently unsatisfactory. Cryosurgery is a less common but effective means of treating these recalcitrant lesions. Freeze times of 30 seconds are required over 1-month interval sessions until flattening is achieved. Zouboulis et al. reported a prospective study of 93 keloids and hypertrophic scars treated with 30-second freeze times over one to three sessions.[9] Improved responses were seen in patients treated with three or more sessions (79 percent), compared with subjects treated once or twice (33 percent).

Dermatofibroma

Treatment times may be 60 seconds due to the fibrotic nature of the lesion and the need to treat cells located in the deep dermis. A retrospective study of 393 dermatofibromas treated with cryosurgery reported 65 percent clearance of a visible and palpable lesion.[12]

Sebaceous Hyperplasia

Mucocele

Verrucae

Warts are a common problem, with a high prevalence in the population.[14] Although cryosurgery for warts has sustained a common practice in dermatology,

▲ **FIGURE 247-2** Warts on hand treated with liquid nitrogen.

varying techniques have been offered with regard to freezing method, number of freeze-thaw cycles, and frequency of treatment sessions. Cryosurgery using the spray technique is probably the most common method due to its quick, convenient use and ease of obtaining a freeze halo around the lesion (Fig. 247-2). The cotton-tip applicator technique is cheaper and may be less frightening to the patient, particularly children. Care must be undertaken not to cross-contaminate by reintroducing the cotton-tip applicator into a common flask.

Combination therapy with cryosurgery has also been advocated to treat verrucae. Berth-Jones and Huchinson[21] demonstrated a 52 percent cure rate at 3 months with the combination of cryotherapy, keratolytic wart paint, and paring. The authors also noted that paring the wart before cryotherapy improved the cure rates for plantar warts, but not hand warts.

Actinic Keratosis

Cryosurgery is an effective modality for the treatment of actinic keratoses (AKs). The open spray technique, using a single freeze-thaw cycle of 8 to 10 seconds, is the treatment of choice (Fig. 247-3). Hypertrophic AKs require longer freeze times while atrophic AKs and AKs on thin-skinned regions require shorter freeze times. A 1- to 2-mm freeze margin around the lesion is adequate. For thicker lesions, pre-treatment of emollients or curetting may shorten freezing times.

CRYOSURGERY FOR MALIGNANT LESIONS

Cryosurgery appears useful in well-defined lesions for situations where surgery is less favorable, either for technical or cosmetic reasons, or when the patient prefers this treatment option.

Cryosurgery is not indicated for lesions that require histology diagnosis at the same time of treatment or have ill-defined borders, atypical pigmentation, or low cure rates. The goal of cryosurgery is to cure the patient by destroying the lesion in a single treatment.

Bowen Disease

Basal Cell Carcinoma

Several studies have reported treating basal cell carcinomas (BCCs) with cryosurgery with cure rates ranging between 95 percent and 99 percent.[27–29] Although excellent cure rates have been claimed, few studies have demonstrated histologically that the BCC is no longer present post-treatment. Furthermore, there are no good studies comparing cryosurgery with other known treatment modalities, such as Mohs surgery, excision with clinical margins, and electrodesiccation and curettage.

Postsurgical cosmetic appearance is a concern to patients. Kokoszka and Scheinfeld[32] reported good cosmetic results in their review of the literature. Thissen et al.,[33] however, compared the cosmetic results of surgical excision compared with cryosurgery for BCCs of the head and neck and concluded that cosmetic results after excision are better than after cryosurgery.

Squamous Cell Carcinoma

Similar cure rates to BCCs are evident when treating squamous cell carcinomas (SCCs) with cryosurgery. In a study of 563 primary SCCs, of which most were between 0.5 and 1.2 cm in diameter, Graham and Clark[34] reported a cure rate of 97.3 percent. Treatment technique with cryosurgery for SCCs is the same as for BCCs.

Lentigo Maligna

With proper patient selection, cryosurgery can be an effective treatment option for lentigo maligna (LM) due to the sensitivity of melanocytes to cold. With the aid of a Wood's lamp, a clinical margin of 5 mm is drawn around the visible borders of the lesion. The lesion is subsequently treated with a double freeze-thaw cycle of 30 to 60 seconds each cycle. Because atypical melanocytes may extend along the length of the hair follicles, treatment must freeze the tissue to this depth.

Stevenson and Ahmed[35] reviewed cure rates from more than 200 LMs treated with cryotherapy, with an overall recurrence rate of less than 9 percent. However, the recurrence rates in these studies ranged from 0 percent to 50 percent.

▲ **FIGURE 247-3** Actinic keratosis on forehead treated with liquid nitrogen.

Advantages of cryotherapy for LM include its efficiency and avoidance of large surgical scars. One major disadvantage of cryosurgery is the inability to assess whether the lesion has been completely destroyed. In addition, because no tissue is obtained for definitive confirmation of cancer removal, the chance exists that recurrent melanoma may develop and that it may be invasive. Overlying scars may conceal the cancer.

Kaposi Sarcoma

POSTOPERATIVE CARE

Patients should be given simple verbal and written wound care instructions post-treatment. Edema, vesicles, bullae, and weeping should be expected from treated areas within 24 hours post-treatment. Treated sites may be rinsed with soap and water and patted dry with a towel daily. If actively weeping, the wound site may be bandaged. Benign and pre-malignant lesion-treated sites heal typically in 1 to 2 weeks, with malignant lesion-treated sites requiring 3 to 4 weeks of healing.

COMPLICATIONS FROM CRYOSURGERY

Pain

In addition to pain during freezing, patients may also experience discomfort several hours post-treatment. Typically, pain is controlled with acetaminophen. Lesions such as periungual warts, digital lesions, or mucous membrane lesions may require stronger analgesics due to intense swelling and throbbing. If the temple region is treated, patients may experience migraine-type headaches.

Bleeding

Patients on anticoagulant therapy should be warned of bruising due to tissue necrosis. If painful hemorrhagic bullae form, they may be drained with an 18-gauge needle inserted into the lateral blister skin. Care should be undertaken not to remove the surface of the bullae, as this tissue acts as a natural wound dressing.

Pigment Changes

Hypopigmentation is the most disconcerting complication post-cryosurgery. As previously described, pigmented cells are sensitive at temperatures of –4°C to –7°C (24.8°F to 19.4°F). Although hypopigmentation is usually transient, prolonged freezing greater than 30 seconds may result in permanent pigment loss. Topical steroids, glycolic acids, retinoids, and hydroquinone may aid in reducing the incidence of hypopigmentation.

Scarring

Infection

Nerve Damage

Treatment of lesions overlying nerves, such as the postauricular nerve on the neck or digital nerves on medial and lateral fingers and toes, may result in regional paresthesia or motor dysfunction. Digital neuropathy occurring post-cryosurgery of digital warts has been reported.[37]

Alopecia

Mucosal Loss

Insufflation of Soft Tissue

Syncope

Pyogenic Granuloma

ELECTROSURGERY

Electrosurgery is a technique that uses the transmission of electricity to cut tissue, destroy tissue, and cauterize vessels. Variations in current wavelength result in different biologic effects on tissue. For cutaneous procedures, electrosurgery can be categorized into six different treatment modalities: electrofulguration, electrodesiccation, electrocoagulation, electrosection, electrocautery, and electrolysis.

Principles of Electrosurgery

Electrosurgical equipment uses either direct or alternating current. In direct current, electrons flow in one direction, while in alternating current, electron flow reverses direction. With the exception of electrocautery or electrolysis, electrosurgical units used in dermatologic procedures have high-frequency alternating current.

See eFig. 247-3.1 in on-line edition for several examples of electrosurgical units. The terms *monopolar* and *bipolar* refer to the number of tissue-containing tips at the end of a surgical electrode. Monopolar denotes one tip, and bipolar denotes two tips.

Monoterminal refers to the use of a treatment electrode without an indifferent or dispersing electrode. *Biterminal* refers to the use of both treatment and indifferent electrodes.

Modalities of Electrosurgery

ELECTROFULGURATION Electrofulguration uses a damped sine wave, high-voltage, low-amperage alternating current to generate a spark from a monoterminal electrode to the tissue via the air. There is no contact between the electrode and the tissue. This modality is the least tissue damaging of all of the high-frequency electrosurgery techniques, resulting in rapid tissue healing. Most of the tissue damage is superficial, primarily involving the epidermis.

ELECTRODESICCATION Electrodesiccation uses a damped sine wave, high-voltage, low-amperage alternating current to generate a current from direct contact of a monoterminal electrode to the tissue. Superficial tissue damage occurs as heat is transferred to tissue, causing cell death. The extent of tissue damage is directly related to electrode contact time with the skin. Although skin injury is greater with electrodesiccation compared to electrofulguration, most of the tissue damage remains superficial.

ELECTROCOAGULATION Electrocoagulation uses a moderately damped sine wave, low-voltage, high-amperage alternating current to generate a current from direct contact of a biterminal electrode to the tissue. Tissue damage is deeper than with electrofulguration and electrodesiccation, providing tissue coagulation through the generation of heat in the tissue.

Another distinguishing feature of electrocoagulation is the involvement of the patient within the circuit. This allows the use of a lower voltage and higher amperage to generate more coagulation.

ELECTROSECTION Electrosection uses an undamped or slightly damped sine wave, low-voltage, high-amperage alternating current to cut tissue with minimal peripheral heat damage. The "Bovie" knife incorporates a blended undamped and damped sine wave that provides both cutting and coagulation at the same time.

ELECTROCAUTERY Electrocautery uses a heating filament tip connected to a low-voltage, high-amperage direct current,

usually a battery. Heat is transferred from the filament to the target tissue, causing protein denaturation and tissue coagulation. There is no electric current transfer to the target tissue, and the patient is not part of the circuit loop.

Electrocautery is most used for patients with pacemakers or implantable cardiac defibrillators (ICDs) who are high-risk candidates for receiving electrosurgery. In addition, because patients are not part of the circuit loop, electrocautery is useful for non-conductive tissue areas of the body, such as the cartilage, bone, and nails.

ELECTROLYSIS Electrolysis uses low-voltage, low-amperage direct current from a negative electrode to the positive electrode. The negative electrode is applied to the target tissue where electrons are released. The electrons interact with the tissue to produce sodium hydroxide and hydrogen gas resulting in tissue liquefaction. Acids are produced at the positive electrode resulting in tissue coagulation. The main use of electrolysis is for hair removal.

Patient Selection and Indications for Electrosurgery

When taking preoperative history for surgery, patients should be asked if they have a cardiac pacemaker or ICD. High-frequency electrosurgery may interfere with their function or damage the pacemaker or defibrillator, resulting in patient morbidity or mortality.

Patients commonly present for cutaneous surgery with either a cardiac pacemaker or an ICD. Although technologic advances, such as titanium shielding, have provided safeguards against electromagnetic interference (EMI), electrosurgical devices may cause these cardiac devices to malfunction.

Fixed-rate pacemakers are not influenced by EMI from electrosurgery.

ICDs deliver an electrical response to an abnormal ventricular rhythm. Some ICDs have a combination of a pacemaker and defibrillator to respond to both bradycardia and tachycardia. EMIs from electrosurgical devices may mimic a cardiac arrhythmia and cause the unit to discharge.

Recommendations have been published for the preoperative and intraoperative management of patients with pacemakers and ICDs during dermatologic surgery.[39–43]

First, patients with pacemakers or ICDs need to be identified before the surgical procedure. Patients should be asked when scheduling surgery if they have one of these devices. If present, a preoperative evaluation by the patient's cardiologist should be arranged before the surgical procedure. The evaluation should include the scope and location of the surgery, the potential for exposure to EMI, the type of implantable device in the patient, and whether the patient is pacemaker dependent.

For management of patients with pacemakers or ICDs undergoing surgical procedures, consider the use of alternative means of hemostasis such as patient-applied manual pressure[44] or electrocautery. These hemostasis methods do not interfere with implantable cardiac devices and, for short surgical procedures with minimal bleeding, are quite effective.

Complications resulting from using electrosurgery for cutaneous surgery in patients with pacemakers or ICDs are uncommon.

Clinical Applications of Electrosurgery

HEMOSTASIS The most common application of electrosurgery is its use in maintaining hemostasis in the operative field. Different techniques of electrosurgery can be used based on the type of electrosurgical unit used during surgical procedures. Coagulation can be achieved using electrofulguration electrodesiccation, or electrocoagulation by direct application of the electrode to the bleeding vessel. This provides conduction of heat to the vessel, resulting in tissue coagulation (Fig. 247-4).

Alternatively, vessels can be grasped by a forcep or hemostat, followed by application of the active electrode. When electrical current is placed against the metal instrument, heat is transferred from the electrode through the metal tip to the vessel. This technique is best used

▲ **FIGURE 247-4** Electrodesiccation of bleeding vessel during Mohs surgery.

▲ **FIGURE 247-5** Electrocurrent applied to forcep to cauterize bleeding vessel during Mohs surgery.

when the surgical field cannot be visualized due to bleeding (Fig. 247-5).

ELECTROSURGERY OF BENIGN LESIONS Electrodesiccation is an effective treatment modality for papular or plaque-like tumors of the epidermis, such as seborrheic keratoses, verrucae, dermatosis papulosis nigra, molluscum, or flat warts. First, the area around the lesion is anesthetized with lidocaine containing epinephrine. Then, the lesion is touched with the low-power electrode until a gray, superficial charred layer involves the entire lesion. The charred tissue is removed from the treated lesion by wiping with a sterile gauze or curetting. The process is repeated until the lesion is removed at the level of the surrounding skin. This method results in minimal bleeding and scarring because just the epidermal components are removed.

ELECTRODESICCATION AND CURETTAGE OF MALIGNANT LESIONS Curettage and electrodesiccation (C+D) is a commonly used treatment option for BCCs and SCCs. Certain tumor characteristics, however, should be present to ensure high cure rates and acceptable cosmetic outcome. Tumors should be primary, have distinct clinical borders, be located on sites of low recurrence such as the trunk, extremities, or non-"H"-zone regions of the face (see Chaps. 155 and 245), have a superficial or nodular histologic sub-type, and have a diameter of < 1 cm on the face and < 2 cm on the trunk and extremities. In addition, C+D is a viable treatment option for patients with high morbidity co-factors that make surgical excision too risky, or for patients who cannot make regular follow-up visits.

Tumors not acceptable for C+D include those with indistinct borders, tumors on the "H"-zone of the face, tumors

▲ **FIGURE 247-6** Clinical outline of skin tumor before curettage and electrodesiccation.

with an aggressive histologic pattern, tumors with high metastatic potential, and tumors that require histologic diagnosis. For patients with cardiac pacemakers or ICDs, electrocautery may be substituted for electrodesiccation.

The tumor outline should be marked, and lidocaine with epinephrine should be injected to provide adequate local anesthesia (Fig. 247-6). With firm counter-pressure, the lesion is then curetted in a checkerboard pattern until the clinical appearance of the lesion is removed (Fig. 247-7). This is followed by electrodesiccation on high power of the base and periphery of the lesion (Fig. 247-8). This C+D procedure is repeated up to two more times until a resultant atrophic defect without clinical evidence of residual tumor is achieved. Some advocate the inclusion of a 2- to 4-mm rim of clinically normal skin during the C+D procedure, and individual variations of the protocol are established. If curettage of the BCC extends into subcutis, then an extensive invasion of a BCC has occurred, and excision should be performed.

The advantages of treatment with C+D include time-efficiency, ease of surgical technique, and minimal post-treatment morbidity. Disadvantages of treating with C+D include non-confirmation of histologic tumor clearance, practitioner-dependent efficacy, and potentially long (3- to 4-week) healing times via second intention healing. Furthermore, the cosmetic result may show hypopigmentation, atrophy, persistent erythema, and hypertrophic scarring.

Postoperative Care

For all treatment groups, wound areas should be covered with a pressure bandage consisting of a topical petroleum product directly on the wound, an overlying nonstick bandage, and firmly applied gauze with adhesive tape. After 24 to 48 hours, the pressure bandage is removed, and the wound site is cleaned with tap water or saline gently rinsing over the wound. Petroleum jelly and bandage is changed daily after rinsing, for 3 to 4 weeks or until healed.

Complications of Electrosurgery

Although electrosurgery is safe, the surgeon must recognize several dangers while using this technique.

▲ **FIGURE 247-7** Curettage of skin tumor during curettage and electrodesiccation procedure.

▲ **FIGURE 247-8** Electrodesiccation of skin tumor during curettage and electrodesiccation procedure.

BURNS There are several situations in which burns may occur with electrosurgery. Thermal injury can occur if there is inadequate contact between the patient and the dispersing electrode plate, when there is inadvertent contact between the dispersing electrode and the patient or surgeon, and if the patient or surgeon may "ground" himself or herself by touching a metal component of the table. Metal jewelry near the electrosurgical site should also be removed.

FIRE Electrosurgical current will ignite flammable substances like alcohol. When prepping the patient before electrosurgery, non-flammable disinfectants such as iodine or chlorhexidine should be used. In addition, electrosurgery should not be used near the presence of nasal cannulas, masks, or endotracheal anesthesia administering oxygen. Finally, care should be taken not to ignite paper surgical drapes in the surgical field.

CHANNELING High-frequency electrosurgical current can be conducted along neurovascular bundles, causing pain and tissue damage distant to the local electrosurgical site. Using low-current settings or bipolar forceps may minimize this.

INFECTION AND MUTAGENICITY A plume of smoke is generated during electrosurgery. This traveling plume has been shown to contain carbonized tissue and blood, airborne particles, and various chemicals and gases. In addition, smoke created from treating lesions such as warts may contain infectious material, such as bacteria and viruses that may transmit infection.

No known long-term risk for neoplasia or infection is known. The Occupational Safety and Health Administration recommends that surgical smoke be removed and properly filtered by a smoke evacuation system as close to the surgical site as possible.[64] Furthermore, protective equipment, such as face shields and respiratory masks, should be worn during electrosurgery.

CHAPTER 248

Surgical Complications

Richard Bennett

Surgical complications are unexpected problems that arise is association with an operation. Although the surgeon is always vigilant to minimize complications, adverse outcomes will inevitably occur. This chapter focuses on preventing, identifying, and treating common complications seen with skin surgery.

COMPLICATIONS AT THE TIME OF SURGERY

Most complications that occur on the day of surgery involve the patient's underlying medical problems, reactions to administered anesthetics, and bleeding. Allergy, hypersensitivity, or toxic reactions to local anesthetics and fainting with or without seizure can also occur. Although there may be some overlap between these issues, each will be discussed separately.

Patient's Medical Problems

Before surgery, it is important to obtain a medical history and perform a physical examination. The level of physical examination is commensurate with the extensiveness of the surgery that is planned. For example, a small cyst excision would only require a cursory physical exam (i.e., general appearance) and vital signs, whereas an extensive liposuction procedure using a large volume of tumescent anesthesia would require a full physical examination and diagnostic testing, if indicated.

The patient's medical history, including allergies, medications, and past surgeries, is important to obtain. Medications such as anticoagulants, pain medications, and certain herbs can affect bleeding at the time of surgery (Table 248-1).[1,2] Excessive bleeding with prior surgeries, especially if requiring transfusions, can be associated with a prolonged bleeding time. It is important to determine if the patient has a cardiac pacemaker, defibrillator, or any other implantable medical devices. Also, if the patient has an artificial heart valve or a rheumatic heart valve, preoperative antibiotics will be required.

Some of the common problems associated with skin surgery include fainting, seizures, and diaphoresis. Fainting is almost always a vasovagal reaction, and the best treatment is to position the patient in the Trendelenburg position. Seizures sometimes occur with the vasovagal reaction and are short lived. Usually, when patients faint, there is a history of fainting episodes, pointing out the importance of inquiring about this in the medical history. Diaphoresis may occur associated with a vasovagal reaction, angina, or hypoglycemia.

Certain equipment is necessary to address emergencies. A "crash cart" includes a heart monitor with defibrillator and common medications to manage emergencies. Oxygen tanks with appropriate masks or nasal cannulas should be ready for use and checked regularly. In addition, a blood pressure cuff, heart rate monitor, and pulse oximeter should be available. Although we now live in a "911" culture, the operating physician is still responsible for handling medical problems, and the dermatologic surgeon should be certified in basic or advanced cardiac life support. Furthermore, ancillary staff should be similarly certified and know their role in emergency situations.

Anesthesia-Related Complications

Because almost all cutaneous surgery performed by dermatologists is done with local anesthetic, this section only discusses local anesthetic complications. Fortu-

SURGICAL COMPLICATIONS AT A GLANCE

- Complications in dermatologic surgery are relatively uncommon.
- Complications are best avoided by
  - Obtaining patient history of medications, prior bleeding episodes, allergies, and prior surgeries.
  - Observing asepsis during procedure.
  - Gentle handling of tissue.
  - Complete cessation of bleeding at time of surgery.
  - Good wound care by patient after surgery.

TABLE 248-1
Medications That Inhibit Platelet Function

- Persantine

- Nonsteroidal anti-inflammatory drugs
  - Piroxicam
  - Diclofenac
  - Fenoprofen
  - Meclofenamate
  - Phenylbutazone
  - Indomethacin
  - Sulindac
  - Tolmetin
  - Ibuprofen
  - Ketoprofen
  - Naproxen

nately, problems with local anesthetics are extremely rare. Thus, physicians have been lulled into a false sense of security. Allergy to lidocaine (Xylocaine®) is rare if it happens at all; generally the allergy is to the paraben preservative.[3]

Problems with local anesthetics are most often related to the total dosage and the addition of epinephrine (see Chap. 243). The total dosage (for a 70-kg patient) should not exceed 500 mg of lidocaine if epinephrine is used and 200 mg if epinephrine is not used.[4] Alternative anesthetics such as bupivacaine (Marcaine®) have a different recommended total dosage. The initial sign of lidocaine toxicity is tongue and circumoral numbness. If this occurs, oxygen should be administered and an intravenous line established.

The addition of epinephrine to local anesthetics is commonplace. However, epinephrine can cause an increase in heart rate, increased contractility of heart muscle, and vasoconstriction. This phenomenon often occurs with inadvertent direct injection into a blood vessel or if the patient is hyperthyroid. Epinephrine should be given cautiously in patients with severe hypertension or cardiac arrhythmias. In these situations, epinephrine, which is present in prepackaged anesthetic in a dilution of 1:100,000, can be diluted further to 1:200,000 or less without decreasing hemostasis. If patients have a history of sensitivity to epinephrine, it is best to use lidocaine without epinephrine. However, in the absence of epinephrine, the anesthetic duration and level of anesthesia will decrease, and the onset time will increase. Also, the absence of epinephrine in local anesthetic can contribute to increased intraoperative bleeding.

Anesthetic containing epinephrine should not be injected into the digits. Although there is some controversy about this, a patient with unknown diabetes may be at high risk for tissue necrosis. Anesthetic containing epinephrine may be injected into the nose, earlobes, and penis; however, it maybe preferable to do a pudendal block in the latter site.

Bleeding

During and after surgery, a cardinal goal is to minimize blood loss. A medical history helps to identify medical problems that might promote bleeding, such as thrombocytopenia, coagulopathy, or hypertension. Several medications inhibit platelet function (see Table 248-1). Anticoagulants should be specifically queried. Extensive intake of garlic, ginkgo, vitamin E, and some other herbs can promote bleeding. During surgery, meticulous hemostasis will help minimize postoperative bleeding.

One medication with specific importance in dermatologic surgery is warfarin (Coumadin®). Patients on warfarin should not discontinue this medication before cutaneous surgery. In some patients who stop and start warfarin, the blood becomes hypercoagulable, which may lead to blood clots or strokes.[5] Aspirin, on the other hand, is generally safe to stop 10 to 14 days before surgery, unless the patient has had a history of strokes or transient ischemic attacks.[6]

COMPLICATIONS IN THE IMMEDIATE POSTOPERATIVE PERIOD

Some specific complications occur from the day of surgery until approximately 1 to 2 weeks later. It is important to give the patient a way to immediately contact the physician in case complications arise, and it is prudent to call the patient the day after surgery to inquire how he or she is doing.

Infection

Wound infection can occasionally occur despite every effort to adhere to appropriate surgical technique. Three types of infection occur most commonly with cutaneous surgery: *Streptococcus pyogenes*, *Staphylococcus aureus*, and *Mycobacterium* (especially *M. fortuitum* and *M. chelonei*).[7,8] Generally, all three are quite different in clinical presentation and timing. *Streptococcus* occurs early, within 24 to 48 hours of surgery, and appears as a spreading, painful erythema. *Staphylococcus* infection appears at 2 to 5 days after surgery and is usually associated with pus formation. Finally, *Mycobacterium* infection appears 2 to 4 weeks after surgery.[7] Clinically, it appears as ulcerating papules or nodules that will not heal or that repeatedly heal and break down.

Recently a particular form of *S. aureus* resistant to methicillin, so-called *methicillin-resistant S. aureus*, has appeared in an increasing number of wounds.[9] It is therefore important to culture wounds that appear infected so that the proper antibiotic can be selected. Antibiotics that generally work well against methicillin-resistant *S. aureus* are doxycycline and trimethoprim-sulfamethoxazole.

Infections with herpes simplex or herpes zoster are rare after cutaneous surgery. One exception to this is the development of herpes infection after whole-face dermabrasion or laser resurfacing. With these procedures, an antiviral medication, such as acyclovir, valacyclovir, or famciclovir, should be started before surgery, especially in those patients who have a history of herpes simplex infections (see Chap. 193).

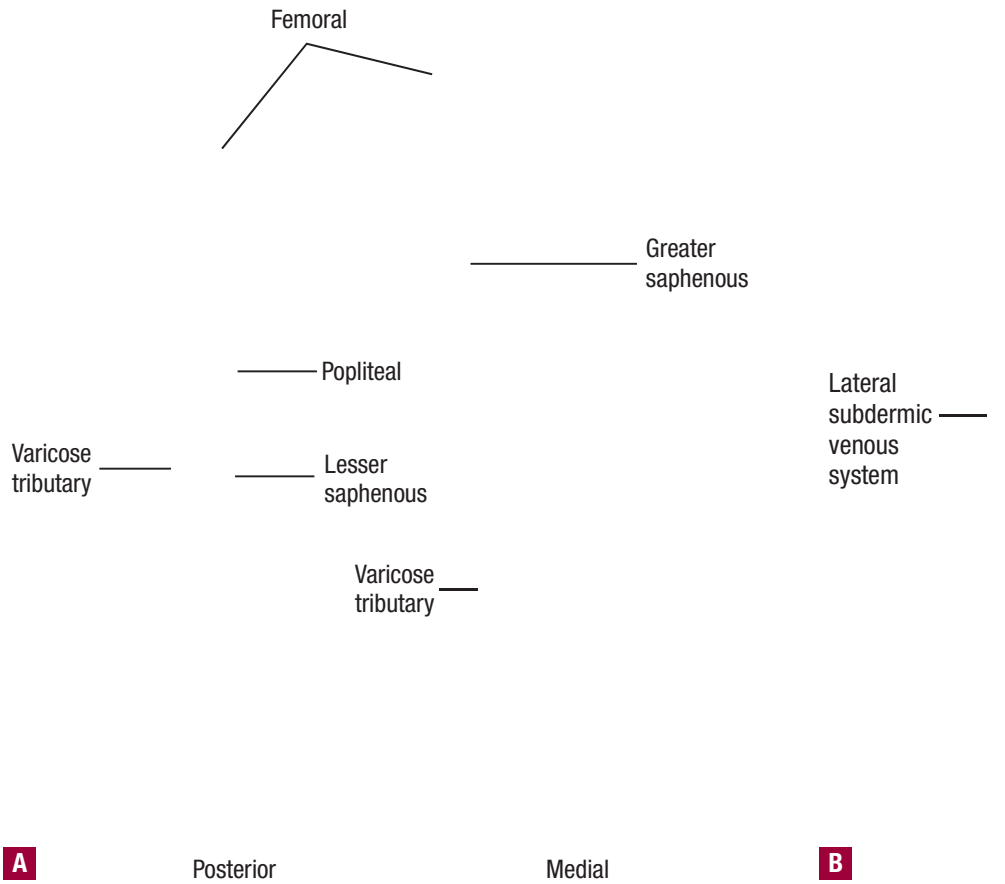
Contact Dermatitis

Allergic reactions can occur to antibiotic ointments used in routine wound care to keep wounds moist. The patient most often has a contact allergy to neomycin or bacitracin.[10] Although bright-red, poorly marginated erythema appears around the operative site with the antibiotic allergy (Fig. 248-1), the diagnosis is usually obvious because the patient will complain of marked pruritus. This symptom is in contrast to that of an infection where the patient complains mainly of pain and pruritus is minimal or absent. Allergic reactions to bandage materials such as Telfa® and Micropore® paper tape are extremely rare.

Pain

Significant pain is rarely present after cutaneous surgery. Patients should take plain acetaminophen for uncomplicated

◀ **FIGURE 248-1** Contact dermatitis to Polysporin® ointment near skin flap.



▲ **FIGURE 250-2** Schematic of the major portions of the superficial venous system. **A.** Greater saphenous vein and lesser saphenous vein. **B.** Subdermic lateral venous system. When varicosities or telangiectatic webs are present within the distribution of these saphenous veins, the source of pressure must be elucidated. The lateral venous system is the most common source of telangiectasias.

mary sources of high, reverse-flow pressure. A high rate of recurrence for sclerotherapy is commonly seen when reflux originates at the major saphenous junctions. The techniques of endovenous occlusion by radio-frequency (RF) or laser are the means by which reflux occurring at the termination point of the saphenous veins is now treated. Five-year data indicates that these techniques are as effective as the old surgical techniques of ligation and stripping to eliminate saphenous veins.[25] Recent studies show high recurrence rates (30 percent to 50 percent) after ligation and stripping.[26] The archaic stripping techniques are no longer recommended for primary treatment of saphenous reflux. With high safety and efficacy of endovenous ablation techniques proven, overwhelming patient preference against stripping, and the reduction of risks by procedures not performed with general anesthesia, endovenous ablation techniques have been embraced.[27]

Venous treatment is contraindicated in a bedridden patient because ambulation is important for minimizing risks of thrombosis. Similarly, patients under general anesthesia for non-related procedures should not undergo simultaneous sclerotherapy. Severely restricted arterial flow to the legs necessitates postponement of vein treatment. A history of deep venous thrombosis (DVT) or previous trauma to the leg (e.g., auto accident) should preclude sclerotherapy until adequately evaluated by duplex ultrasound. Previous urticaria or suspected allergy to a sclerosing agent should serve as a relative contraindication to use of that particular sclerosing agent.

Pregnancy should be considered a contraindication during the first and second trimester, although extremely painful or bleeding varices may be treated in the last trimester by endovenous ablation techniques. Treatment is typically postponed because varicosities and telangiectasias may resolve spontaneously 1 to 6 months postpartum.

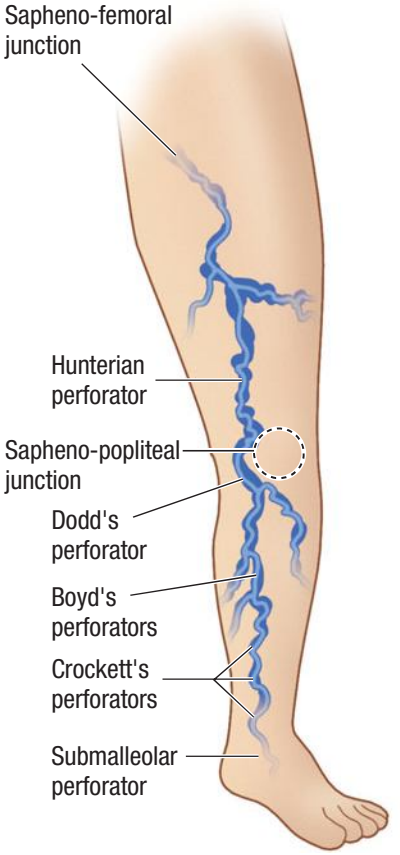
Obesity should be considered a relative contraindication because maintaining adequate external compression is difficult. Sclerotherapy of larger varicosities should be postponed until weight reduction is achieved. During hot summer months, heat-induced vasodilatation and inability to comply with wearing of compression hose may also require postponement of treatment.

TREATMENT TECHNIQUES

Pre-Treatment Evaluation

Physical examination is performed by viewing the patient's legs in a 360° rotation. Palpation is performed along the saphenous vein distributions to rule out early large axial varicosities, which cannot be seen. Based on the history and physical examination, non-invasive, diagnostic vascular tests are performed as necessary.[28] Those patients with a family history of large varicose veins are more likely to have early axial (saphenous) reflux even when presenting with telangiectasias alone.[11] Previous venous surgery warrants further testing before treatment.

Once the patient is judged to be a candidate for vein treatment, informed consent is obtained. Any veins visible or palpable suggestive of saphenous system involvement should be minimally evaluated by hand-held Doppler ultrasound,



▲ **FIGURE 250-3** Diagram indicating major junction points of the superficial venous system with the deep venous system. Larger varicose veins may originate from any of these points.

which is equivalent to using an enhanced "stethoscope" to hear vein flow. To generate or augment an audible signal of flow, a maneuver such as manual compression of the calf must be performed by the examiner. When compression is released, gravitational hydrostatic pressure causes reverse flow to cease within 0.5 to 1.0 second when valves are competent, but a long flow sound is audible when valves are incompetent.

The most essential part of the Doppler examination is the examination of the sapheno-femoral junction below the inguinal fold just medial to the femoral arterial signal. During a Valsalva's maneuver, a continuous and pronounced reflux signal is a reliable sign of valvular insufficiency. An equivocal result may require a duplex ultrasound examination for a definitive answer. Methods of complete Doppler examination are detailed in other texts or papers.[11]

The gold standard of non-invasive examination of the venous system is duplex ultrasound. This allows direct visualization of the veins and identification of flow through venous valves. An image is created by an array of Doppler transducers that are switched on and off sequentially. The duplex examination is often used to uncover hidden sources of reflux prior to beginning any method of treatment or to delineate reflux sources when patients experience poor results from sclerotherapy.

TABLE 250-1
Indications and Contraindications for Sclerotherapy

INDICATIONS	CONTRAINDICATIONS
• Pain	• Reflux at sapheno-femoral or sapheno-popliteal junction[a]
• Major tributaries of greater and lesser saphenous veins	• Non-ambulatory patient
• Major perforator reflux	• Obesity
• Lateral venous system varicosities	• Deep venous thrombosis
• Cosmetic	• Known allergy to sclerosing agent
	• Arterial obstruction
	• Pregnancy

[a]Relative contraindication, success has been reported under the right conditions, proper sclerosing solutions (not available in United States) and/or the use of duplex-guided sclerotherapy.

Endovenous Chemoablation Solutions

Sclerosing solutions have been classified into groups, based on chemical structure and effect: hyperosmotic, detergent, and corrosive agents (chemical toxins—salts, alcohols, and acid or alkaline solutions). Commonly used sclerosing solutions are summarized in Table 250-2.

Sclerotherapy Technique

A basic principle of treatment is to begin at the largest (reflux sources) and progress to the smallest varicosities and then finally to telangiectasias. When present without larger varicosities, telangiectasias are approached by combined injection of visibly connected reticular veins, venulectases, and telangiectatic webs or networks. Reticular veins are treated only after all sources of reflux from major varicosities have been treated by sclerotherapy and/or surgery. When no clear feeder vessel is seen or identified by Doppler, transillumination (Veinlite, 3Gen, Dana Point, CA) is another method that may be used to identify the "feeding" reticular vein. (Fig. 250-4). When unable to locate an associated reticular vein, then the point at which the telangiectasias begin to branch out is the site at which to begin injection. Injection of telangiectasias is simultaneously performed with injection of reticular veins in the hopes of decreasing the number of treatments.[33]

The injection method for telangiectasia is basically as previously described by Duffy and Goldman.[16,34] The sclerotherapy tray is prepared with the necessary equipment (Table 250-3). A 30-gauge needle, bent to an angle of 10° to 30° with the bevel up, is placed on the skin so that the needle is parallel to the skin surface. A 3-cc syringe filled with 1.5 to 2.0 cc of solution is held between the index and middle fingers while the fourth and fifth fingers support the syringe against the leg in a fixed position facilitating accurate penetration of the vessel. The non-dominant hand is used to stretch the skin around the needle and may offer additional support for the syringe (Fig. 250-5). Magnifying lenses or operating loops on the order of 1.5 to 3.0× may help cannulation of the smallest telangiectasias.

The initial treatment of telangiectatic webs begins with lowest possible concentration that will cause a telangiectasia to sclerose over a period of 1 to 6 months postinjection. This typically is 0.1 percent sodium tetradecyl sulfate (STS) or 0.2 percent polidocanol (POL). The use of 50 percent to 72 percent glycerin in water is becoming increasingly frequent in our practice. When ineffective sclerosis occurs, judged at a subsequent visit, the concentration but not the volume per site of sclerosing solution is increased. Post-treatment compression consists of graduated 20 to 30 mm Hg or 30 to 40 mm Hg support hose for 2 weeks for larger veins and over-the-counter (nonprescription) 15 mm Hg compression for smaller veins. Treatment intervals vary, but allowing 4 to 8 weeks between treatments helps to minimize the number of necessary sessions. Typical results are shown in Fig. 250-6.

FOAM SCLEROTHERAPY Foam sclerotherapy has become a standard of treatment, as the foam completely fills and displaces the blood in the vein. The microbubbles of foam allow maximal contact with the highest concentration of the sclerosant, thereby resulting in maximal endothelial cell injury and subse-

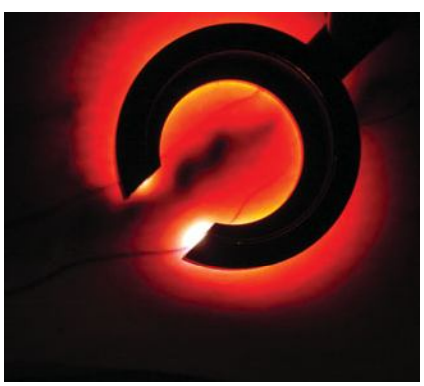
TABLE 250-2
Comparison of Commonly Used Sclerosing Agents

Sclerosing Solution	Category	Advantages	Disadvantages	Vessels Treated	Concentrations
Sodium tetradecyl sulfate (Sotradecol)	Detergent	FDA approved Painless—unless injected extravascularly	May cause breakdown rarely—found to be equivalent to polidocanol in clinical studies	All sizes	0.1%–0.2% telangiectasias 0.2%–0.5% reticular 0.5%–1.0% varicose 1.0%–3.0% axial varicose
Polidocanol	Detergent	Painless Low ulceration risk at low concentrations	Not FDA approved	Small to medium	0.25%–0.5% telangiectasias 0.5%–1.0% reticular 1.0%–3.0% varicose
Hypertonic saline	Hyperosmolar	Low risk of allergic reactions	Ulcerogenic Painful to inject	Small	23.4%–11.7% telangiectasias 23.4% reticular
Hypertonic saline + dextrose (Sclerodex)	Hyperosmolar	Low risk of allergic reaction Mild stinging Low ulcerogenic potential	Not FDA approved Relatively weak sclerosant	Small	Undiluted—telangiectasias Undiluted—reticular
Sodium morrhuate (Scleromate)	Detergent	FDA approved	Allergic reactions highest	Small	Undiluted—telangiectasias Undiluted—reticular
Chromated glycerin (glycerin with 6% chromium salt; Scleremo)	Chemical irritant	Low skin ulcer potential	Not FDA approved Very weak sclerosant	Smallest	Undiluted to one-half strength—telangiectasias
Glycerin—plain	Chemical irritant	Painless, low risk of allergic reaction, decreased risks of pigmentation and matting	FDA approved for reduction of cerebral edema	Smallest	50%–72%
Polyiodinated iodine (Varigloban)	Chemical irritant	Highly corrosive—allows treatment of largest veins	Not FDA approved Avoid in iodine-allergic patients	Largest	1%–2% for up to 5-mm veins 2%–6% for the largest veins

FDA = U.S. Food and Drug Administration.

quent fibrosis of the vein wall. This results in more effective sclerotherapy, which leads to fewer treatment sessions. Less total amount of solution is required with foam. This has the additional benefit of decreasing systemic toxicity. An additional advantage of foam is that duplex-guided sclerotherapy becomes more precise, as the foam is very echogenic and easily visualized on ultrasound.

The most used technique for foam sclerotherapy is the Tessari technique.[35]



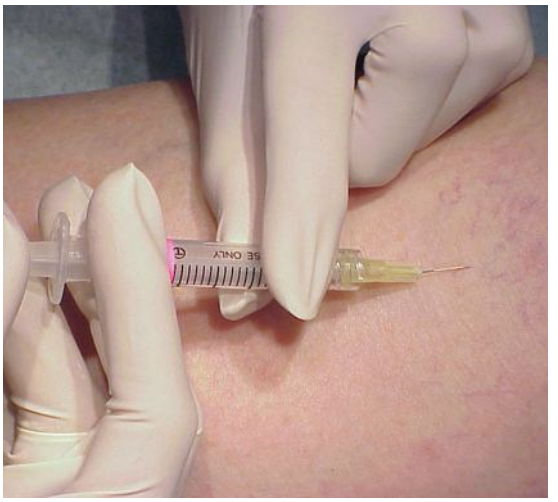
▲ **FIGURE 250-4** Transillumination of a reticular vein. The reticular vein shows up as a dark curvilinear object against a light background.

Two, 3-cc Luer-Lok syringes are connected with a disposable three-way stopcock. One syringe is filled with air, and one syringe is filled with a detergent type of sclerosant. The optimal ratio of solution to air is 1:4. The contents of the syringes are shifted back and forth quickly approximately 10 to 20 times and the turbulent flow generates the foam (Fig. 250-7). The foamed solution should be used immediately because it degrades within 60 to 90 seconds. The nature of the foam allows for the same therapeutic effect with approximately one-half the concentration of sclerosant. For instance, one can substitute 0.1 percent STS foam for 0.2 percent STS liquid. Lower concentrations are used for all size veins. Foamed solution should only be used for varicosities, perforating veins, reticular veins, and larger telangiectasias (1 to 2 mm). Smaller telangiectasias run the risk of increased pigmentation and matting, as more inflammation occurs with the relatively increased concentration interacting with the vein wall.[36]

TABLE 250-3
Sclerotherapy Tray

- Cotton balls soaked with 70% isopropyl alcohol
- Protective gloves
- 3-cc disposable syringes
- 30-g disposable transparent hub needles
- Cotton balls or foam pads for compression
- Transpore™ and/or paper tape
- 2% nitroglycerine paste (for prolonged blanching or extravasation)
- Sclerosing solutions:
  - Sodium tetradecyl sulfate (ranging concentrations, 0.1%–0.5%)
  - Hypertonic saline (11.7%–23.4%)
  - Hypertonic saline (10%) and dextrose (25%) (may be mixed by local pharmacy)
  - Polidocanol (0.25%–1.0%) (pending U.S. Food and Drug Administration clearance)
  - Three-way stopcock to foam solutions (1:4—sclerosant-air)

SIDE EFFECTS AND COMPLICATIONS OF SCLEROTHERAPY ***Post-Sclerotherapy Hyperpigmentation.*** Post-sclerosis pigmentation is defined as the appearance of increased visible pigmentation along the course of a treated vein of any size. Initially, perivascular hemosiderin deposition and not increased melanin production causes this appearance[37]; however, over time



◀ **FIGURE 250-5** Position of the hands for sclerotherapy. While the dominant hand holds the syringe and creates a platform with the fifth digit, the non-dominant hand stretches the skin and acts as a support for the needle hub so that fine changes in position are permitted.

the hemosiderin is replaced by melanin. The incidence of pigmentation is related to dilution and type of sclerosing agent as well as diameter of treated vessel.[38] Pigmentation incidence ranges from 11 percent to 30 percent using hypertonic saline,[24] 11 percent to 30 percent with POL,[16,39] and up to 30 percent with STS. The incidence of pigmentation may be reduced in varicose veins by expressing the dark, viscous blood thought to be a liquefied coagulum or intravascular hematoma, which may accumulate 1 to 4 weeks after sclerotherapy.

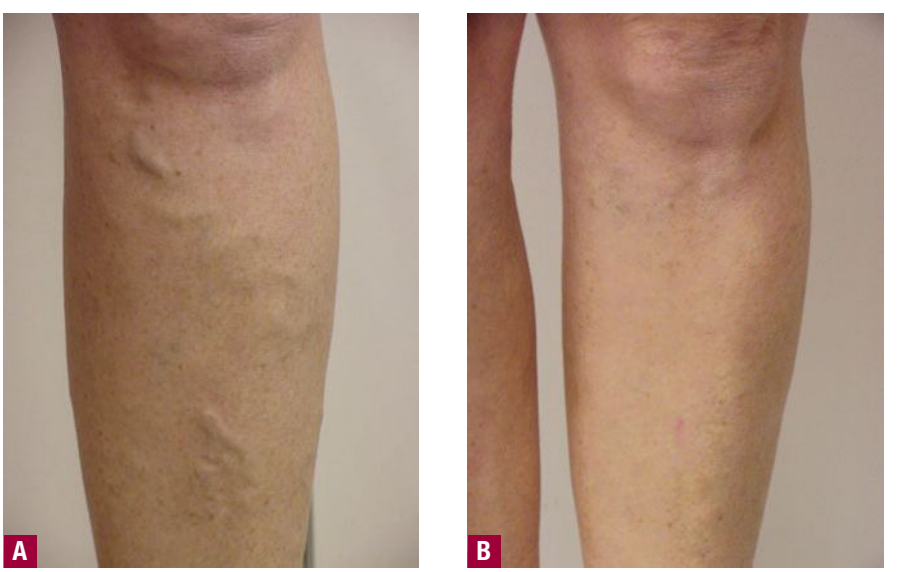
Pigmentation clears in 70 percent within 6 months but rarely persists for greater than 1 year.[38] Attempts to hasten resolution of pigmentation have been mostly unsuccessful, as the pigment is dermal hemosiderin and not epidermal melanin. Bleaching agents, exfoliants such as trichloroacetic acid or phenol, cryotherapy, various lasers, and intense pulsed light have achieved limited success.[40,41] The Q-switched ruby laser has been found to be the most consistently effective for treatment of postsclerosis pigmentation (see Chap. 240).[42]

Telangiectatic Matting. Telangiectatic matting is defined as the appearance of groups of new, fine (< 0.2-mm diameter) telangiectasias surrounding or replacing a previously treated area in a blush-like manner. A retrospective analysis of over 2000 patients reports an incidence of 16 percent in patients treated with hypertonic saline and POL.[43] Resolution usually occurs spontaneously within a 3- to-12-month period with 70 percent to 80 percent spontaneous resolution within the first 6 months.[44]

Cutaneous Necrosis and Ulceration. Cutaneous ulceration may occur with all sclerosing solutions in spite of the most skilled technique. Unavoidably, a tiny amount of sclerosing solution may be left along the needle tract as the needle is withdrawn. Sclerosing solution may also leak out into the skin through the small puncture sites of vessel cannulation. The varicose vein may have a fragile, thin wall, with the injection causing rapid injury, leading to sudden unexpected rupture with perivascular accumulation of sclerosant. Additionally, injection may inadvertently occur into a small arteriole associated with telangiectatic varicosities with resultant necrosis and ulceration.

When the dermatologic surgeon recognizes that extravasation has occurred, the risk for necrosis can be minimized by injecting normal saline in a ratio of 10:1 over sclerosant into the extravasation site. Extensive massage of small subcutaneous blebs to spread the trapped sclerosing agent as quickly as possible will minimize prolonged blanching of the area. We have found that application of topical 2 percent nitroglycerine paste applied immediately to the suspected extravasation site greatly reduces the risks of necrosis but will not always prevent it.

Superficial Thrombophlebitis. This complication is most commonly mistaken for the normal nodular fibrosis (endosclerosis) that occurs with proper sclerotherapy. After sclerotherapy, a non-tender, non-pigmented, nonerythematous fibrotic cord may normally be palpable along the course of a treated 4- to 8-mm vein. This frequent finding is due to a liquefied intravascular hematoma with surrounding vein wall sclerosis and is not a thrombosis. In contrast, superficial thrombophlebitis is characterized clinically by a very tender, indurated, linear erythematous swelling. Incidence of superficial thrombophlebitis is quite variable estimated at 1 percent to 0.01 percent after sclerotherapy,[47] although a recent report indicates that the inci-



▲ **FIGURE 250-6** Typical results after sclerotherapy. **A.** Large varicose vein treated twice with 0.5 percent sodium tetradecyl sulfate. **B.** Excellent clinical results at 15-month follow-up.

▲ **FIGURE 250-7** Generation of foam for sclerotherapy. Vigorous agitation between two syringes results in a frothy material for injection. Reduced total amounts of sclerosing solution with decreased total volumes results in increased safety.

dence is higher than previously suspected.[48] Treatment consists of leg elevation and/or compression and regular administration of aspirin or other nonsteroidal anti-inflammatory drugs. Extension of superficial thrombophlebitis into the deep system is extremely rare.

Pulmonary Embolism. Pulmonary emboli probably occur from extension of a superficial thrombus into the deep venous system. Evidence of extension from superficial thrombus to deep thrombophlebitis should be treated promptly by anticoagulation. The incidence of pulmonary embolism has been associated with injection of large quantities of sclerosant at a single site. The incidence is extremely low with less than 1 in 40,000.

Arterial Injection. This dreaded medical emergency is fortunately extremely rare. Classic warning signs include immediate intense pain far beyond the normal discomfort at the initiation of injection, although leakage of sclerosant into the arterial circulation may present in an atypical fashion. Continuous intense burning pain with immediate bone-white, cutaneous blanching over an area of several square centimeters is the usual initial sign. Progression to a sharply demarcated cyanosis within minutes is typical for arterial injection. Emergency treatment involves immediate application of ice, attempts to flush the inadvertently injected artery with normal saline and/or heparin, injection of 3 percent procaine to inactivate STS, and vascular surgery consultation for intravenous anticoagulation. Rarely, arterial injection may not be accompanied by any pain or cutaneous signs. The atypical cases are suspected to arise from arteriovenous malformations.[49] Arterial injection may lead to wide areas of skin necrosis and damage to subcutaneous tissue and muscle, which take months to heal.

MINIMAL SURGICAL APPROACHES FOR VARICOSE VEINS

Endovenous Ablation and Occlusion Techniques

Endovenous ablation techniques were first developed by dermatologic surgeons.[14,50] When it has been determined by ultrasound that the originating point of reverse flow or reflux is the great saphenous vein or short saphenous vein, endovenous RF or laser techniques are used, as ligation and stripping are being phased out. When saphenous system reflux is present, the endovenous occlusion techniques must be performed before treatment of visible and associated varicosities, reticular veins, or telangiectasias. Without elimination of reflux, the patient will be doomed to recurrence after recurrence.

Radio-Frequency

The efficacy for RF elimination of reflux is 90 percent at 2 years and 80 percent at 5 years.[17,25] This method involves the placement of a catheter or fiberoptic within the varicose vein through a small puncture or incision. The catheter is threaded up to the sapheno-femoral junction typically under duplex ultrasound guidance. Critical to the safety and success of the technique is placement of tumescent local anesthesia, which involves first infiltrating the tissue under the skin including thigh muscles to push the saphenous vein further away from the skin and then creating a space between the fascia and the saphenous vein so as to hydro-dissect the vein away from structures such as nerves and arteries. Once this hydro-dissection has been performed with high volume, low concentration of local anesthetic (0.1 percent lidocaine), energy is applied as the catheter is slowly withdrawn. This results in heat directly applied to the vein wall via a computer-controlled thermo-couple feedback loop. This results in a collagen shrinkage accompanied by complete vein wall occlusion.

Laser (Hemoglobin Predominant Absorption—810-nm, 940-nm, 980-nm)

Endovenous laser treatment is similar to RF in that energy, which ultimately releases heat to produce endothelial and vein wall shrinkage, results in subsequent fibrosis. The target for lasers with 810-, 940-, and 980-nm wavelengths is intravascular red blood cell absorption of laser energy. These techniques are highly dependent on correct placement of tumescent local anesthesia so as to protect surrounding nerves from injury. Direct thermal effects on the vein wall without the presence of blood probably do not occur. The extent of thermal injury to tissue is strongly dependent on the amount and duration of laser energy application. Multiple factors that affect outcome include blood in the lumen, rate of pullback, and amount of tumescent anesthesia placed around the vein.

One in vitro study model showed that thermal gas production by laser heating of blood in a 6-mm tube results in 6 mm of thermal damage.[51,52] Histologic examination of one excised vein demonstrated thermal damage along the entire treated vein with evidence of perforations at the point of laser application described as "explosive-like" photo-disruption of the vein wall. This produced the homogeneous thrombotic occlusion of the vessel. Formation of bubbling blood is the proposed mechanism of action for heating surrounding tissue.[52] We have found that superheating of blood during these procedures occurs to a maximum of approximately 1200°C (2192°F).[18]

These endovenous lasers have short-term efficacy of 90 percent occlusion over the first year, but the rate decreases with time.[53,54] In addition, most patients experience major degrees of postoperative ecchymosis and discomfort. Saphenous nerve injury, skin burns, and DVT have occurred due to the high temperatures of blood heating from these wavelengths, although the overall safety and efficacy record is better than for stripping.[55–57] The incidence of these complications is lower with RF endovenous occlusion.

Laser (Water Predominant Absorption—1320 nm)

A variation of the endovenous laser, 1320 nm, was developed by dermatologic surgeons in an attempt to bypass the problems associated with laser wavelength absorption of hemoglobin. Tissue water is the target, and the presence or absence of red blood cells within the vessels is unimportant. For more controlled release of laser energy, it is coupled with an automatic pullback device variable from 0.5 to 1.0 mm/sec. The penetration of the 1.32-μm wavelength is unique, with far less heat and risk than with the hemoglobin-absorbing wavelengths.

Endovenous ablation appears to be best accomplished not by hemoglobin heating but by heating water within collagen in the vein wall as a target. Proebstle et al. demonstrated a statistically reduced rate of postoperative pain accompanied by a higher initial success rate using 1320 nm versus 940 nm.[58] Our own experience reflects this, with a reduction in pain and bruising of 80 per-

▲ **FIGURE 250-8** **A.** Endovenous ablation of the great saphenous vein results in the improvement of associated varicosities (**B**).

cent when switching from 810-nm endovenous to 1320-nm endovenous. Having treated over 200 greater saphenous veins with 1320 nm, our incidence of mild pain is 5 percent. No significant pain interfering with walking has been observed, which occurred with 50 percent of 810-nm treatment. A clinical example of varicose veins resulting from reflux at the sapheno-femoral junction pre- and post-treatment is shown in Fig. 250-8.

Ambulatory Phlebectomy

Ambulatory phlebectomy, originally described by Robert Muller and further refined by another Swiss dermatologist (Albert-Adrien Ramelet), involves the use of tiny incisions through which the varicose vein is removed by a small hook.[59,60] This safe, outpatient local anesthesia technique allows removal of almost any varicose vein except the sapheno-femoral or sapheno-popliteal junction, which are treated initially by endovenous ablation techniques. Areas or veins that are resistant to foam sclerotherapy are particularly indicated for ambulatory phlebectomy (see eFig. 250-8.1 in on-line edition). Risks that are minimized compared with sclerotherapy are DVT, post-sclerotherapy pigmentation, skin necrosis, and superficial phlebitis. In many cases, larger varicose veins co-exist with smaller reticular veins and associated telangiectatic webs. It is reasonable to treat larger varicose veins by various surgical techniques and follow up with sclerotherapy of the remaining reticular networks.

Lasers and Light Sources (See Chaps. 240 and 253)

New trends for improved results with lasers and light sources for spider veins include longer wavelengths, larger spot sizes, and cooling to protect the skin (Fig. 250-9). The first report of 1064-nm neodymium:yttrium-aluminum-garnet (Nd:YAG) laser indicated that 75 percent improvement was possible after a single treatment at 3 months.[61] These findings were confirmed and the mechanism of action explained as heat-induced vessel damage and subsequent fibrosis.[62] Recent reports also indicate effectiveness of 940-nm diode laser.[63] Shorter wavelengths used in the past, like pulsed dye laser, have limited use on leg veins, although many devices are now being adapted to longer pulse durations up to 40 ms. In our practice, the vast majority of laser treatments are performed using 1064-nm Nd:YAG laser in the millisecond domain on isolated telangiectasias, sclerotherapy-resistant telangiectasias, ankle telangiectasias, and suspected arteriovenous malformations. Even associated reticular veins with telangiectasias can be treated with 1064 nm; however, the larger the vein, the more painful the treatment due to increased absorption of infrared energy.[64]

▲ **FIGURE 250-9** Clinical results with 1064-nm laser. A small isolated group of telangiectasias are treated with 1064-nm laser (Vasculight, Lumenis, Santa Clara, CA). **A.** Before and (**B**) 3 months after treatment. Treatment parameters are single, 16-ms pulse, 6-mm spot size, 120 J/cm^2.

SECTION 41

COSMETIC DERMATOLOGY

CHAPTER 251

Cosmetics and Skin Care in Dermatology

Leslie Baumann

According to recent data, U.S. sales of skin care cosmeceuticals (cosmetics with attributed biologic effects) were approximately $6.4 billion, and it is estimated that the skin care market will reach $7.2 billion by 2010.[1,2] A plethora of skin care products are currently available to account for this substantial sales volume. The range of products and their associated claims are so extensive and complex that physicians and consumers are often confused about their indications and effectiveness. One approach to understanding these many options is to consider how the products are used to treat specific skin types.

For purposes of cosmetics, facial skin can be grouped into four main categories that, in practice, represent up to 16 skin types: dry or oily; sensitive or resistant; pigmented or non-pigmented; and wrinkled or unwrinkled (or "tight"). These "skin types" are not static and can be affected by a range of intrinsic and extrinsic factors such as environment, aging, and disease. The key to proper skin care recommendations is to take all four parameters into consideration. The various permutations of the four skin-type parameters yield 16 possible skin types. For example, a person may have dry, sensitive, pigmented, wrinkled skin, and her needs would significantly differ from someone with oily, sensitive, pigmented, and wrinkled skin. These skin types are not to be confused with the Fitzpatrick photo-skin types (see Chap. 89).

This chapter will discuss the basic science and defining characteristics of the four parameters. Certain extrinsic or intrinsic factors, such as a move to a different climate, a change in stress levels, pregnancy, menopause, and others, can result in a skin-type change. The Baumann Skin Type Indicator, a questionnaire developed to determine skin type, is helpful in assessing skin type initially and again after major life changes.[3]

SKIN HYDRATION

Oily versus Dry

Xerosis or "dry skin" describes skin that is characterized by dull color (usually gray white), rough texture, and an elevated number of ridges.[4] The etiology of this common condition is multifactorial. The most significant factor in the development of xerosis is the role of the stratum corneum (SC) and its capacity to maintain skin hydration. Rawlings et al. showed that patients with dry skin have a perturbation in the lipid bilayer of the SC that is associated with increased fatty acid and decreased ceramide levels.[5] Defects or deficiencies in this barrier layer of the skin cause a spike in water evaporation, known as trans-epidermal water loss (TEWL) (see Chap. 45).

The SC is composed of three primary groups of compounds: ceramides, fatty acids, and cholesterol. When present in the proper amount and balance, these components help to protect the skin and keep it watertight. When the barrier is impaired, however, the skin is rendered dry because of the inability to retain water and sensitive because of increased vulnerability to extrinsic elements. Several other factors play a causative role in dry skin.

Natural moisturizing factor (NMF), derived from the breakdown of the protein filaggrin, is integral in maintaining water within skin cells. Filaggrin provides structural support and strength in the lower layers of the SC. It is broken down in higher levels (stratum compactum) of the SC by a still-uncharacterized cytosolic protease into free amino acids, including histidine, glutamine (glutamic acid), and arginine.[9] These osmotically active amino acids remain inside the keratinocyte and avidly bind to water. The pace at which filaggrin is broken down into NMF is thought to be regulated by aspartate protease (cathepsin), which initiates this cascade and determines the amount of NMF that is present.[10] Interestingly, this putative aspartate protease (cathepsin) is regulated by changes in external humidity. In other words, in low humidity environments, the pace of NMF production increases. This acclimation process typically occurs over the course of several days[11] and cannot yet be regulated artificially via products or procedures.

Hyaluronic acid (HA), which can bind 1000 times its weight in water, is another substance found in the skin that

COSMETICS AND SKIN CARE AT A GLANCE

- Nonmedical skin care and cosmetic use of over-the-counter products represent major growth areas among consumers.
- Understanding variations in skin types using a new system of classification facilitates patient section of over the counter products.
- Cosmetics and skin care products can be a source of a range of adverse reactions, including irritation and allergy.

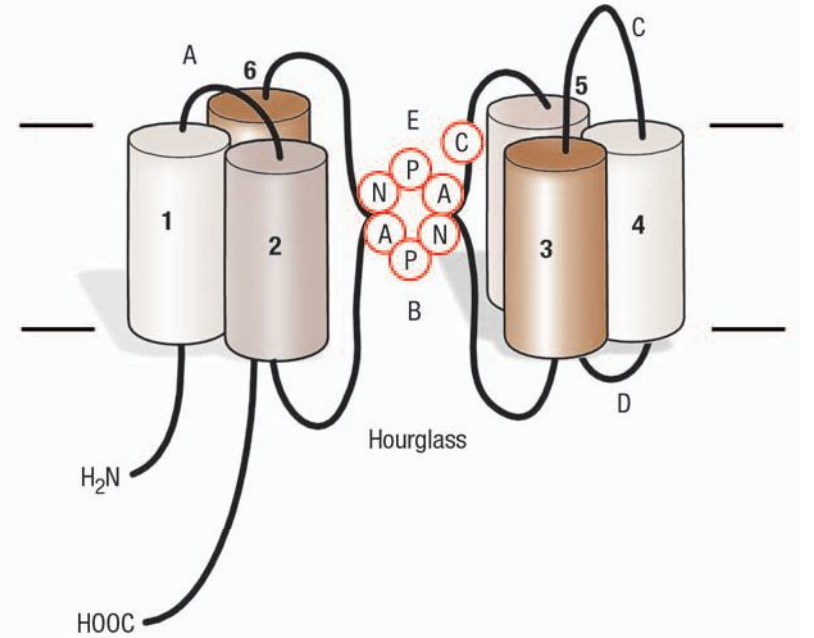
may help it retain and maintain water. HA is produced mainly by fibroblasts and keratinocytes in the skin, and has an estimated turnover rate of 2.0 to 4.5 days in mammalians.[12] HA is localized not only in the dermis but also in the epidermal intercellular spaces, especially the middle spinous layer, but not in the SC or stratum granulosum.[13] Aged skin, which is less plump than youthful skin, is characterized by decreased levels of HA. The role of HA in skin hydration is not clear, and HA does not penetrate the skin upon topical application[14]; however, this has not stopped many companies from putting HA in topical skin care products and claiming efficacy.

Aquaporin-3 (AQP3) is a member of a family of homologous aquaporin water channels that facilitate fluid transport. Other aquaporins in this family are well known to play a role of water transport in kidney and lung epithelia. AQP3 is a member of a subclass of aquaporins called aquaglyceroporins, which transport not only water but also glycerol and possibly other small solutes. AQP3 was recently found to be expressed at the plasma membrane of epidermal keratinocytes in human skin (Fig. 251-1).[15] Pharmacologic manipulation of AQP3 may be used in the future to treat skin disorders of excess and decreased hydration. At this time, only *Ajuga turkestanica* extract has been shown to play a role in regulating AQP3.[22] *A. turkestanica* is found as an ingredient in a high-end line of skin care products.

Sebum production may also be a factor in the pathogenesis of xerosis. The oily secretion of the sebaceous glands contains wax esters, sterol esters, cholesterol, di- and triglycerides, and squalene,[23] and is thought to confer protection to the skin from environmental influences and, when production is decreased, play a part in dry skin (see Chap. 77).[24] In normal skin, sebaceous gland–derived triglycerides are hydrolyzed to glycerol before delivery to the skin surface. Replacing this glycerol in sebum-deficient skin may be a way to decrease skin dryness in sebum-deficient individuals. Glycerol has also been shown to be effective in accelerating barrier recovery.[32]

Patients rarely complain about decreased sebum production. However, it seems certain that sebum production plays a role in dry skin. For example, prepubertal children (> 2 years and < 9 years) commonly display eczematous patches (pityriasis alba) on the face and trunk that disappear coincidentally with the onset of sebaceous gland activation. Conversely, increased sebum production, which results in oily skin that can lead to acne, is a common complaint. It is well understood that an age-related change is seen in sebaceous gland activity, with levels typically low during childhood, rising in the mid- to late teens, and generally remaining stable for decades until trailing off in the seventh and eighth decades as endogenous androgen production declines.[33] The level of sebum production is also influenced by diet, stress, hormone production, and, to a degree, genetics. In a study of 20 pairs each of identical and non-identical like-sex twins, the identical twins exhibited essentially the same sebum excretion rates, with significantly divergent acne severity, whereas the non-identical twins differed significantly according to both parameters, implying both the genetic influence of sebum and the mediation of exogenous factors in lesion development.[34]



▲ **FIGURE 251-1** Hourglass model for aquaporin-1 membrane topology. Each aquaporin-1 subunit contains six bilayer-spanning domains composed of two obversely symmetric structures (TM1–3, hemipore 1; and TM4–6, hemipore 2). When NPA [formed by amino acids asparagine (N), proline (P), and alanine (A)] motifs in loops B and E are juxtaposed, they form a single aqueous channel spanning the bilayer (the "hourglass") flanked by the mercury-sensitive residue (C189). Skin Care for the Oily-Dry Parameter

In the context of the oily-dry parameter, ideal skin is typically characterized by an intact SC with an intact barrier, sufficient NMF levels, normal levels of HA, normal expression of AQP3, and balanced sebum secretion. In skin that falls on the oily side of the equation, increased sebum secretion is usually the culprit. This may or may not be accompanied by acne. If acne is a concern, then the patient would also fall into the sensitive skin category and would be labeled as an oily-sensitive skin type. The skin care treatments would focus on decreasing sebum with retinoids, decreasing skin bacteria with antibiotics, benzoyl peroxide, or other antimicrobials, and adding anti-inflammatory ingredients. If acne is not a problem, the individual would be labeled as an oily-resistant skin type. The skin care would focus only on decreasing sebum production unless other parameters such as dyspigmentation and wrinkling were factors. Oral ketoconazole[35] and oral retinoids[36] have been shown to decrease sebum secretion, but this has not been shown with topical agents. Sebum-absorbing polymers and talcs are also useful to camouflage unwanted sebum in these types.

In skin that falls on the dry side of the equation, one must decide which factors are contributing to the dry skin. Clues can be derived by looking at the other skin parameters. If a patient is dry and sensitive, it is likely that the skin barrier is impaired, and care should be taken to use products that repair the skin barrier,

such as those that contain fatty acids, cholesterol, ceramides, and glycerol. If the skin is photodamaged and the skin is wrinkled as a result, decreased HA likely plays a role. Topically applied HA is not absorbed, so using skin care products with HA is not helpful; however, studies have suggested that glucosamine supplements may help increase HA levels.[37] One small single-blind study showed improvement of wrinkles but no change in skin hydration, so the role of glucosamine is unclear.[38] Dry skin that endures ongoing sun exposure likely suffers from an impaired skin barrier and decreased levels of NMF. At this time, there are no products that increase NMF, so skin care should focus on repairing the skin barrier and providing adequate sun protection.

All patients with dry skin are advised to avoid harsh foaming detergents that remove hydrating lipids and NMF from the skin. These detergents are found in laundry and dish cleansers in addition to body and facial cleansers. All dry skin patients should also abstain from taking protracted baths, particularly in hot or chlorinated water. In addition, people with very dry skin are advised to use humidifiers in low-humidity environments and apply moisturizers two to three times a day and after bathing.

In addition to targeting the causes of dry skin, there are many moisturizers on the market that help hydrate the skin in a more basic or generic manner. These products can be categorized as occlusives, humectants, or emollients (Table 251-1).

TABLE 251-1
Types of Ingredients in Moisturizers for Topical Skin Care

- Barrier repair
  - Ceramides
  - Cholesterol
  - Fatty acids
- Occlusives
  - Petrolatum
  - Mineral oil
  - Paraffin
  - Squalene
  - Dimethicone
  - Soybean oil
  - Grapeseed oil
  - Propylene glycol
  - Lanolin
  - Beeswax
- Humectants
  - α-Hydroxy acids
  - Glycerin
  - Hyaluronic acid
  - Propylene glycol
  - Sodium hyaluronate
  - Sorbitol
  - Sugars
  - Urea

OCCLUSIVES Occlusives coat the SC to retard TEWL. An occlusive provides an emollient effect as well as decreases TEWL. The best occlusive ingredients currently available are petrolatum and mineral oil. Petrolatum, for example, has a water vapor loss resistance 170 times that of olive oil.[39] However, petrolatum has a greasy feeling that may make agents containing it cosmetically unacceptable. Other commonly used occlusive ingredients include paraffin, squalene, dimethicone, soybean oil, grapeseed oil, propylene glycol, lanolin, and beeswax.[40] These agents are only effective while present on the skin; once removed, the TEWL returns to the previous level. Interestingly, it is not desirable to decrease TEWL by more than 40 percent because maceration with increased levels of bacteria can result.[41] Therefore, occlusives are usually combined with humectant ingredients.

HUMECTANTS Humectants are water-soluble materials with high water absorption capabilities. They are able to attract water from the atmosphere (if atmospheric humidity is greater than 80 percent) and from the underlying epidermis. Although humectants may draw water from the environment to help hydrate the skin, in low-humidity conditions, they may absorb water from the deeper epidermis and dermis, resulting in increased skin dryness.[42] For this reason, they are more effective when combined with occlusives. Humectants are also popular additives to cosmetic moisturizers because they prevent product evaporation and thickening, which increases the shelf-life of products. Some humectants have bacteriostatic activity as well.[43] Humectants draw water into the skin, causing a slight swelling of the SC that gives the perception of smoother skin with fewer wrinkles. Examples of commonly used humectants include glycerin, sorbitol, sodium hyaluronate, urea, propylene glycol, α-hydroxy acids, and sugars.

EMOLLIENTS Emollients are substances added to cosmetics to soften and smooth the skin. They function by filling the spaces between desquamating corneocytes to create a smooth surface.[44] These products provide increased cohesion, causing a flattening of the curled edges of the individual corneocytes.[45] This leads to a smoother surface with less friction and greater light refraction. Many emollients function as humectants and occlusive moisturizers as well. Lanolin, mineral oil, and petrolatum are examples of occlusive ingredients that also confer an emollient effect.

SKIN SENSITIVITY AND COSMETIC INTOLERANCE SYNDROME

Sensitive versus Resistant

Sensitive skin is much more challenging to describe than resistant skin. The latter is characterized by a strong SC that confers potent protection on the skin, shielding it from allergens and irritating substances. As the term implies, resistant skin rarely exhibits erythema (unless over-exposed to the sun) or acne (unless it is so affected due to stress or hormonal fluctuations). People with resistant skin can use most skin care products without fear of developing an adverse reaction such as a rash, acne, or a stinging sensation. The disadvantages of such skin include an inability to detect different effects among cosmetic products and, more important, having too high a threshold for penetration, so that most products are not likely to cross the SC and impart beneficial changes.

The concept and presentation of sensitive skin is much more complex. More than 40 percent of people presenting to a dermatologist report having sensitive skin.[46] Healthy women of child-bearing age comprise the majority of people who complain of this type of skin. With increasing age, the incidence of sensitive skin appears to decline. There are numerous cosmetic products available on the market that are marketed for sensitive skin. However, sensitive skin itself is a relatively complex dermatologic phenomenon.

Cosmetic intolerance syndrome is not a single entity but, rather, a symptom complex of multiple exogenous and endogenous factors, representing an extreme of the continuum of patients who complain of sensitive skin. The syndrome is an uncommon clinical entity in which patients complain bitterly of facial burning and discomfort associated with application of most skin care products. Their skin may show overt inflammatory changes, or symptoms may be only subjective. These patients seriously challenge practitioners' empathy and diagnostic skills because the severity of

symptoms does not match objective signs of disease. Many patients affected with this syndrome have tried numerous cosmetics and topical medications.

Fisher[47] coined the term *status cosmeticus* for the condition in which patients no longer tolerate use of any facial cosmetic product. Some of these patients initially experience subjective or objective irritation in response to use of cosmetics and become intolerant to many other topical agents during the evolution of this disorder. Other patients have occult allergic contact dermatitis, allergic photocontact dermatitis, contact urticarial reaction, or a combination of these conditions. In this group, causal agents can be documented by careful clinical review and patch testing.

Strictly observing a prolonged program of eliminating cosmetics is an important therapeutic intervention. Some patients are able to return gradually to using other cosmetics after 6 to 12 months. Subsequent additions to the skin care regimen can be made one at a time every 2 weeks. For the final regimen, the number of cosmetics and frequency of their use should remain limited.

Other patients experience facial burning continuously, without showing objective signs. Cotterill[48] described these patients as having "dermatologic nondisease." Many of these patients have a disturbed body image or dysmorphobia—that is, they complain of physical defects that lack objective evidence. Many are depressed and need psychiatric help, which they frequently reject.

Sensitive skin covers the same range of pathophysiology as the cosmetic intolerance syndrome, but it is generally less severe. The largest segment of these consumers manifests sensory skin irritation.

Indeed, there are four very distinct variations of sensitive skin: acne type (prone to developing acne, black heads, or white heads); rosacea type (featuring a tendency toward recurrent flushing, facial redness, and experiencing hot sensations); stinging type (predilection to stinging or burning sensations); and allergic type (prone to exhibit erythema, pruritus, and skin flaking).

Each of these sub-types of sensitive skin presents a unique challenge to the practitioner regarding appropriate treatment and recommendations for over-the-counter cosmetic skin care products. The common process among these four sub-types is inflammation. Therefore, treatments for any kind of sensitive skin should focus on reducing and eliminating inflammation. Treatment can be further complicated when a patient exhibits a proclivity towards more than one sensitive skin sub-type.

Acne Type (See Chap. 78)

Some skin and hair care cosmetics cause acneiform eruptions. Acnegenicity encompasses both comedogenicity, which refers to follicular keratin impaction,[51] and papulopustular formation. The time course for the appearance of facial papulopustules and comedones is different: papulopustules may appear in just a few days, whereas the appearance of comedones is delayed. Considerable confusion derives from the testing techniques: for example, isopropyl myristate in concentrations as low as 10 percent in petrolatum rapidly induces comedones in the rabbit ear but yields papulopustules in humans. Even common emulsifiers, such as sodium lauryl sulfate, produce pustules in a dose-related manner. The mechanisms appear to be related in spite of varied morphology. The European Community's proposed ban on animal testing of final products will result in stronger reliance on human testing, whether this takes the form of use tests or application of a cosmetic under occlusion to the back for 4 weeks and subsequent cyanoacrylate or cationic polymer biopsies (to identify microcomedones), or both.

The clinical significance of cosmetics in precipitating post-adolescent acne in women was recently called into question by one of the authors of the original paper on "acne cosmetica."[52,53] Consequently, it is best to advise female acne patients to keep their cosmetic regimen simple and gentle, using products from manufacturers who test for acnegenicity.

Rosacea Type (See Chap. 79)

Typically afflicting adults between 25 and 60 years of age, rosacea affects tens of millions of Americans. Like acne, this condition is characterized by facial redness, flushing, and papules, but it is also distinguished by the formation of prominent telangiectasias. Topical skin care for rosacea is primarily geared toward preventing exacerbation of the condition and using anti-inflammatory ingredients to decrease inflammation. Ingredients with anti-inflammatory activity include feverfew, sulfur, zinc, sulfacetamide, quadrinone, niacinamide, licorice extract, cucumber extract, aloe vera, colloidal oatmeal, and chamomile (Table 251-2).

TABLE 251-2
Anti-Inflammatory Products for Topical Skin Care (Over-the-Counter)

- Licorice extract
- Licochalone
- Quadrinone
- Cucumber
- Aloe vera
- Chamomile
- Colloidal oatmeal
- Arnica
- Feverfew (has anti-inflammatory and antioxidant capabilities)
- Niacinamide (also known as *nicotinamide*)
- Salicylic acid
- Zinc
- Witch hazel

Stinging Type

Burning, stinging, or itching caused by application of a cosmetic or topical medicament without detectable visible or microscopic change is termed *sensory irritation*. The afferent limb of this reaction is carried by C nerve fibers that are present throughout the dermis and viable epidermis. The stinging occurs on the face within 1 hour of application in susceptible individuals. In a segment of the population, this sensory response is caused by many ingredients at dosages that do not produce clinical, objective irritation. Nonallergic stinging is a phenomenon that a discrete subset of people experience in response to certain triggers. Some patients may indeed be more sensitive than others and are referred to as *stingers* by dermatologists. Stingers do not have a higher incidence of atopy or dry skin but do report frequent adverse reactions to cosmetics. Strontium nitrate and chloride inhibit sensory irritation caused by α-hydroxy acids, ascorbic acid, and aluminum salts.[54] These blockers are being incorporated into skin care products such as those containing α-hydroxy acids.

Several tests have been devised to identify stingers or the stinging propensity. The lactic acid stinging test is a widely accepted method for evaluating individuals who report invisible and subjective cutaneous irritation. In an early study, Frosch and Kligman applied 5 percent lactic acid to subjects' nasolabial folds during profuse sweating, which resulted in 20 percent of participants reporting an unpleasant sensation. In a similar study in which lactic acid (10 percent) was applied to nasolabial folds, Seidenari et al. ob-

served that individuals with "sensitive skin" experienced a much stronger stinging sensation than those in the healthy control group. The stinging sensation is not necessarily associated with erythema, as many patients feel stinging without experiencing redness or irritation.[55] However, patients with rosacea distinguished by facial flushing are more susceptible to stinging from lactic acid exposure. It is recommended that patients with the stinging sub-type of sensitive skin avoid products that contain the following ingredients: α-hydroxy acids (particularly glycolic acid), benzoic acid, bronopol, cinnamic acid compounds, Dowicel 200, formaldehyde, lactic acid, propylene glycol, quaternary ammonium compounds, sodium lauryl sulfate, sorbic acid, urea, or vitamin C.

Allergic Type

According to the findings of a recent epidemiologic survey in the United Kingdom, over the course of 1 year, 23 percent of women and 13.8 percent of men experience an adverse reaction to a personal care product (e.g., deodorants and perfumes, skin care products, hair care products, and nail cosmetics).[56] To identify allergies to cosmetic ingredients, patch testing can be performed. Various studies reveal that approximately 10 percent of patch-tested dermatologic patients are allergic to at least one ingredient common in cosmetic products.[56] About 80 percent of reactions occur in patients aged 20 to 60 years old, with the majority seen most often in women.[57] Fragrances and preservatives are the most common allergens. Individuals who use several skin care products with a commensurately high number of ingredients are more likely to develop allergies to ingredients, simply due to such over-exposure. Patients with an impaired SC, manifested by xerosis (the dry skin type), are likely to have an increased incidence of allergic reactions to allergens placed on the skin.[58]

SKIN IRRITATION AND ALLERGY DUE TO COSMETICS AND SKIN CARE PRODUCTS

Skin irritation is defined as localized inflammation that is not mediated through the immune system and is caused by endogenous and environmental factors. Hair straighteners, permanents, and depilatories can cause acute reactions if directions for their safe use are not strictly followed. Cleansers are frequently responsible for causing irritant dermatitis. Moisturizers or emollient creams, in which water and oleaceous materials are blended, contain surfactants and emulsifiers that are often mild irritants. When these cosmetics are applied to the face or to dry or eczematous skin, where the SC is a less efficient barrier, irritant reactions may result. Morphologic features include scaling, which may rapidly clear with avoidance of exposure but becomes erythematous with recurrent dosing and may evolve into chronic irritant dermatitis. Some cosmetics produce irritation only after repeated application; this phenomenon is termed *cumulative irritation*. Friction, injury, and mechanical irritation can be caused by popular cosmetics containing granules or by devices (e.g., synthetic sponges) used to exfoliate the skin (Table 251-3).

TABLE 251-3
Diagnosis and Treatment of Patients Whose Skin Is Intolerant to Cosmetics

- Examine every cosmetic and skin care product.
- Administer patch and photo-patch test to rule out occult allergic and photoallergic dermatitis.
- Test for contact urticaria.
- Do careful repeat open application testing.
- Treat endogenous inflammatory disease.
- Limit skin care to
  - Water washing without soap or detergent
  - Lip cosmetics as desired, if lips are clear
  - Eye cosmetics as desired if eyelids are asymptomatic
  - Face powder
  - Glycerin and rose water as a moisturizer, if necessary
  - Avoiding other cosmetics for 6–12 mo

Sensitive bioengineering techniques used to evaluate the pathophysiology of irritation include TEWL, skin impedance, conductance resistance, and blood flow velocity.[59] By using predictive testing in animals and humans, manufacturers can recognize strong or moderate irritant ingredients or products. In pre-market testing, mild irritants are more difficult to detect and quantify.

Bergamot oil (5-methoxypsoralen) is a phototoxic fragrance ingredient that was used in cosmetics but has been removed. As interest in "natural" ingredients increases,[60] new phototoxins may be inadvertently introduced and have serious consequences when they are not recognized clinically.

OTHER SKIN REACTIONS DUE TO COSMETICS

Contact Urticaria Syndrome (See Chap. 37)

Contact urticaria syndrome typically consists of a wheal-and-flare response developing within 30 to 60 minutes after the skin is exposed to certain agents. Symptoms range from the mildest manifestations (e.g., itching, tingling, burning, and erythema) to the most severe (e.g., anaphylaxis and death). Diagnosis of immediate contact urticaria is based on a thorough medical history (including notation of burn, sting, or itch resulting from skin contact, urticaria, or respiratory symptoms) and skin testing using suspected substances.[61]

Delayed Hypersensitivity Reactions (See Chap. 13)

Adverse reactions to cosmetics constitute a small but significant portion of contact dermatitis cases treated by dermatologists. In a study conducted by the North American Contact Dermatitis Group, patch testing showed contact dermatitis related to cosmetics in 5 percent of more than 13,000 patients evaluated.[63] Similar percentages have been reported from Europe.[61] These figures underestimate the total number of cases because most mild reactions are not investigated by dermatologists. In the North American Contact Dermatitis Group study, 59 percent of the cosmetic-induced reactions occurred on the face, and 79 percent were seen in women, but a relation to cosmetics was suspected by the dermatologist or patient initially in fewer than one-half of the cases. Diagnosis of allergic contact dermatitis is based on a compatible history and examination, supported by results of patch testing. Most cosmetics are not strong irritants and can be patch tested closed in the usual manner; however, notable exceptions exist. Weakly positive reactions should be confirmed by medical history, test repetition, and patch testing of ingredients. Ingredient testing is a problem in the United States because of the limited number of chemicals available on the T.R.U.E. (thin-layer rapid use epicutaneous) test screening tray. It is important to recognize which of these allergens are found in cosmetics. Cosmetic Industry on Call[64] provides information for contacting manufacturers who may provide ingredients for patch testing. De Groot et

al.[65] provide reference information on chemical concentrations and vehicles to use in testing cosmetic ingredients.

The provocative use test, also called the *repeat open application test*,[66] is a practical way to screen for allergy to cosmetics including fragrances[67] or to confirm the clinical significance of weak positive reactions. The cosmetic is applied twice daily for up to 4 weeks to an approximately 5-cm area on the flexor surface of the forearm near the cubital fossa.

Most photoallergic ingredients in cosmetics are sunscreening agents or fragrances. To test for photoallergy, the patch site is exposed to between 5 and 10 J of ultraviolet (UV) A 24 hours after application; after 48 hours, the photopatch site is compared with a nonirradiated site similarly patch tested.

Most allergic reactions to cosmetics are caused by fragrances, preservatives, and a small number of miscellaneous ingredients. Familiarity with these allergens will enable clinicians to diagnose many of these cases accurately (see Table 251-3).

SKIN REACTIONS DUE TO FRAGRANCES

Fragrance allergy is common, affecting approximately 1 percent of the general population; dermatitis may develop on the face, neck, hands, and axillae, or it may be generalized.[68]

Fragrances are ubiquitous: in addition to cosmetics and toiletries, they are added to household goods or cleansers in the workplace, and some are used as flavorings. Paradoxically, "unscented" cosmetics may contain a masking fragrance. A new method of promoting fragrances is to claim that scents have mood-altering effects—so-called *aromatherapy*. Inevitably, troublesome sensitization has occurred in consumers who have doused themselves and their surroundings with fragrance. Since 1966, toxicologic information related to fragrance ingredients has been assembled and assessed by the industry-sponsored Research Institute for Fragrance Materials.[69] Based on this information, the International Fragrance Association publishes guidelines that industry members generally agree to follow.

Photosensitization (see Chap. 91) occurred more commonly before methyl coumarin and musk ambrette were eliminated from fragrances. Sensitization to musk ambrette left an extensive legacy of so-called *persistent light eruptions*. Because fragrance allergy is frequently not suspected by either the patient or the physician, patch testing is an important tool for reaching this diagnosis. Balsam of Peru, cinnamal, fragrance mix, and colophony are recognized markers for fragrance allergy on patch-test screening series. At present, the fragrance mix (marketed by Hermal and by Chemotechnique and also marketed in the T.R.U.E. test) contains eight ingredients: eugenol, isoeugenol, oak moss absolute, geraniol, cinnamal, α-amyl cinnamic aldehyde, hydroxycitronellal, and cinnamic alcohol. In an international study of 165 patients with probable fragrance allergy, the fragrance mix detected 86 percent of positive reactions. Addition of ylang-ylang oil, narcissus oil, sandalwood oil, and balsam of Peru raised this percentage to 96 percent. Racial and geographic distinctions exist; for instance, Japanese patients tested were more frequently reactive to benzyl salicylate. Such racial differences were highlighted by the epidemic of bizarre facial hyperpigmentation seen in Japanese women in the 1960s and 1970s caused by allergy to fragrances and coal-tar dyes used in some cosmetics; elimination of these allergens solved the problem.

Allergy to fragrance can be tested by using the repeat open application test for up to 4 weeks. Balsams, cinnamic alcohol, cinnamaldehyde, benzyl alcohol, and benzaldehyde are among the fragrance ingredients that can evoke contact urticaria not detected by closed patch testing.

SKIN REACTIONS DUE TO PRESERVATIVES

Preservatives are added to prevent contamination of cosmetics by microorganisms, which degrade the product or cause infection in consumers; however, the term *preservative* may encompass agents that prevent degradation induced by oxidation or UV light. Approximately 60 chemicals are commonly used as preservatives in cosmetics. Preservatives may consist of a single ingredient or a mixture of ingredients (e.g., Euxyl 400 is a mixture of methyldibromoglutaronitrile and phenoxyethanol). Use of specific preservatives varies among American, European, and Asian markets; consequently, incidence of allergic reactions to individual agents also varies. Adverse reactions have prompted development of preservative-free cosmetics. Strategies for developing such products include modification of the manufacturing and packaging processes as well as use of botanicals, which have antimicrobial activity. The increasing complexity of cosmetics and their vehicles makes this goal even more difficult to achieve.

Paraben esters, the most popular group of preservatives, are effective against fungi and Gram-positive (but not Gram-negative) bacteria. Parabens rarely sensitize but may do so when applied to eczematous skin. Sensitized patients frequently tolerate parabens in cosmetics applied to normal skin.

Propylene glycol, a popular solvent and humectant, has antimicrobial properties but is used in some "preservative-free" cosmetics. Review of the literature and observations in patch-tested patients suggest that propylene glycol is a mild irritant that only occasionally sensitizes.[70]

Formaldehyde and formaldehyde releasers are widely used as preservatives.[71] Formaldehyde is formulated in wash-off products such as shampoos. Quaternium-15, imidazolidinyl urea, diazolidinyl urea, DMDM hydantoin, and 3-bromo-2-nitropropane-1-3-diol are commonly used preservatives that release formaldehyde. They may sensitize themselves or cause reactions secondary to formaldehyde release in formaldehyde-sensitive patients, and cross-reactions in the group are reported. Patients' tolerance of products containing preservatives to which they are sensitive is modified by the site of application and their degree of sensitivity. For example, some formaldehyde-sensitive individuals can tolerate low levels of formaldehyde releasers on normal skin.

A mixture of methyldibromoglutaronitrile and phenoxyethanol (Euxyl 400), used initially in Europe, has gained popularity and is being reported more frequently as an allergen.[72] Butylated hydroxyanisole, butylated hydroxytoluene, tocopherol, propyl gallate, and t-butyl hydroquinone used as antioxidants are sometimes reported as allergens. Other ingredients reported frequently as allergens in cosmetics include paraphenylenediamine, toluene sulfonamide/formaldehyde resin (tolysamide/formaldehyde resin), acrylates, lanolin, glyceryl thioglycolate, and UV light-absorbing agents (Table 251-4).

SKIN PIGMENTATION

Pigmented versus Non-Pigmented

The third primary skin characterization parameter gauges the tendency to develop unwanted hyperpigmentation or dyschromia on the face or chest. For the purposes of describing a skin type to a patient and assisting the individual in selecting appropriate skin care products, the focus should be on the pig-

mentary changes that can be improved with skin care products rather than surgery. For example, skin care products can be used to prevent or treat conditions such as melasma, solar lentigos, and ephelides. Patients with these concerns would be called pigmented types.

Two primary mechanisms can be used to impede the development of skin pigmentation: inhibiting tyrosinase, which prevents melanin formation, and preventing melanosome transfer into keratinocytes. Tyrosinase inhibitors include vitamin C, hydroquinone, kojic acid, arbutin, mulberry extract, and licorice extract (Table 251-5).

Small proteins found in soy, such as soybean trypsin inhibitor and Bowman-Birk Inhibitor, have been suggested to inhibit skin pigmentation. These soy proteins were found not only to have depigmenting activity, but also to prevent UV-induced pigmentation both in vitro and in vivo.[75] According to Paine et al., these soy proteins were found to exert their effect via the inhibition of the cleavage of protease-activated receptor 2. Protease-activated receptor 2 is a seven transmembrane G-protein coupled receptor that is activated by a serine protease cleavage. It is expressed in keratinocytes but not in melanocytes. By inhibiting this cleavage, soybean trypsin inhibitor and Bowman-Birk Inhibitor are believed to affect melanosome transfer into keratinocytes and, thus, pigmentation. Niacinamide, a derivative of vitamin B_3, has also been shown to inhibit melanosome movement form melanocytes to keratinocytes.[76]

Ultraviolet Radiation and Skin Color

Melanogenesis results from the exposure of skin to UV radiation and serves as the skin's major defense against further UV damage. Melanocyte cells increase the production of melanin, melanocyte transfer from melanosomes to keratinocytes is increased,[77] and this process manifests in exogenous skin darkening. Sun avoidance is the most effective method of preventing pigmentary changes; thus, broad-spectrum sunscreens are an important component of any skin care regimen geared at reducing hyperpigmentation.

SKIN AGING: WRINKLED VERSUS TIGHT (See Chap. 108)

Aging of the skin is a complex phenomenon reflecting natural intrinsic and extrinsic processes. Intrinsic aging is a function of individual heredity and results from the passage of time. This process is, of course, inevitable and beyond voluntary control.

Exogenous factors, such as smoking, poor nutrition, and sun exposure, are at the root of extrinsic aging. This process is not inevitable and reflects premature skin aging. In fact, 80 percent of facial aging is believed to be due to solar exposure.[80] Exposure to UV irradiation, by dint of its damaging effect on DNA and its acceleration of telomere shortening, also can be said to influence intrinsic aging. In addition, UV exposure results in skin damage through several mechanisms, including sunburn cell formation, creation of thymine dimers, collagenase production, and provoking an inflammatory response. Signaling through p53 after telomere disruption is also a common feature observed in aging as well as photodamage.[81] Although much remains to be learned about the mechanisms through which UV irradiation unleashes a chain of cascading health effects, photoaging, photocarcinogenesis, and photo-immunosuppression are well-known results of UV exposure.[82]

The most obvious manifestation of aging skin is the development of rhytides. Wrinkles are caused by changes in the dermis. Although consumers spend millions of dollars on "antiaging" skin care products, few skin care product ingredients can penetrate far enough into the dermis to affect deep wrinkles. The dermatologic focus of antiaging skin care should be to prevent the formation of rhytides in the first place.[83] To this end, the goal is to halt the degradation of the three main structural components of the skin—collagen, elastin, and HA—all of which are known to be diminished in aged skin. Because inflammation can contribute to the breakdown of these key skin constituents, one focus must be to reduce inflammation. Kang et al. have shown that free radical activation of the mitogen-activated protein kinase pathways results in production of collagenase, which leads to degradation of collagen.[85] Blocking this pathway with antioxidants is thought to prevent photoaging by preventing the production of collagenase. Research supporting this theory was performed on human skin by Kang. In this study, he showed that when human skin was pre-treated with the antioxidants genistein and *N*-acetylcysteine, UV induction of the c-jun–driven enzyme collagenase was blocked. Many antioxidants are available in skin care products including vitamin C, vitamin E, ferulic acid, coenzyme Q10, green tea, Pycnogenol, silymarin, and idebenone.

Most antiaging products and procedures are geared to salvage collagen, elastin, and HA. However, products containing collagen, elastin, or HA are ineffective; they cannot effectively penetrate the epidermis. Although there are no products that can replenish these important skin structures, there are some products that stimulate production of these components. Collagen synthesis has been shown to be increased through the use of retinoids,[86] vitamin C,[87] and copper peptide. Retinoids have also been demonstrated in animal models to increase production of HA[88] and elastin.[89] Oral vitamin C is also believed to have the capacity to increase collagen synthesis[90] and, again, glucosamine supplementation may augment HA levels.[91] In the future, it is likely that the potential of growth factors, cytokines, and telomerase will be harnessed through advances in tissue engineering and gene therapy.[92] In the meantime, using sunscreen, avoiding exposure to the sun, cigarette smoke, and pollution, taking oral antioxidant supplements or topical anti-

TABLE 251-6
Baumann Skin Type Determined by the Baumann Skin Type Indicator

	Oily, Pigmented	Oily, Non-Pigmented	Dry, Pigmented	Dry, Non-Pigmented	Sensitive or Resistant
Wrinkled	OSPW	OSNW	DSPW	DSNW	Sensitive
Tight	OSPT	OSNT	DSPT	DSNT	Sensitive
Wrinkled	ORPW	ORNW	DRPW	DRNW	Resistant
Tight	ORPT	ORNT	DRPT	DRNT	Resistant

oxidant formulations, and eating a diet high in fruits and vegetables can help reduce or prevent skin aging. Regularly using prescription retinoids can also help treat and prevent unwanted wrinkles.

COMBINATIONS OF SKIN TYPES

The four skin parameters can be combined to form 16 skin types (Table 251-6). Using this typing system will help consumers focus on their problem areas. For example, an oily, sensitive, non-pigmented, wrinkled person would use products with retinoids and antioxidants, whereas a dry, sensitive, non-pigmented, tight person would use products with barrier repair ingredients. Certain skin problems are more typically associated with particular skin combinations: pigmented, wrinkled skin is more likely exhibited by a person with a significant history of sun exposure manifested by wrinkles and solar lentigos. Eczema is more often observed in dry, sensitive types. Acne is most common among oily, sensitive types. Oily, sensitive, non-pigmented, wrinkled types with lighter skin are most prone to develop rosacea. Light skin is more common among non-pigmented, wrinkled types; dark skin is more common among pigmented, tight types.

CONCLUSION

For the purposes of optimal treatment and cosmetic selection, a classification of skin types that defines four different polarities is suggested: dry or oily; sensitive or resistant; pigmented or non-pigmented; and wrinkled or unwrinkled. Characterizing a patient's skin based on all the permutations and combinations of these skin types (see Table 251-6) can facilitate treatment by physicians and help patients select the most appropriate over-the-counter skin formulations.

CHAPTER 252

Skin Resurfacing: Ablative Lasers, Chemical Peels, and Dermabrasion

Elizabeth L. Tanzi
Tina S. Alster

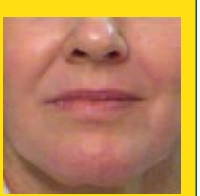
Years of damaging ultraviolet light exposure manifest clinically as a sallow complexion with roughened surface texture and variable degrees of skin dyspigmentation, telangiectasias, wrinkling, and laxity (see Chap. 108).[1,2] Histologically, these extrinsic aging effects are usually limited to the epidermis and upper papillary dermis and, thus, are amenable to treatment with a variety of ablative and non-ablative lasers, chemical peeling agents, and dermabrasion. Although dermabrasion had been used in the past to wound the skin and thus stimulate the production of new collagen, which is a common approach to skin rejuvenation, the advent of lasers and chemical peeling agents has vastly expanded and advanced the options for the treatment of cutaneous photodamage. Which treatment technique is most appropriate depends on the severity of the photodamage and the rhytides, the expertise of the dermasurgeon, and the expectations and lifestyle of the individual patient. Non-ablative laser procedures are discussed in Chap. 253.

ABLATIVE LASER SKIN RESURFACING

Patient Selection

The ideal patient for ablative cutaneous laser resurfacing has a fair complexion

SKIN RESURFACING AT A GLANCE



- Several approaches are available for the rejuvenation of photodamaged skin.
- The most common approaches are ablative and non-ablative laser resurfacing and chemical peels.
- Selection of the appropriate technique requires that patient factors as well as the risks and benefits of the procedure be weighed.

TABLE 252-1
Ablative Laser Skin Resurfacing: Patient Selection, Risks, and Precautions

- Are the lesions amenable to cutaneous ablative laser resurfacing? All suspicious lesions require biopsy before treatment.
- Has the patient ever had the areas treated before? Ablative laser resurfacing can unmask hypopigmentation or fibrosis produced by prior dermabrasion, cryosurgery, or phenol peels. Patients with prior lower blepharoplasties using an external approach are at greater risk of ectropion formation after infraorbital ablative skin resurfacing.
- What is the patient's skin phototype? Patients with lighter skin tones (skin phototype I or II) have a lower incidence of postoperative hyperpigmentation than patients with darker skin tones after ablative laser skin resurfacing.
- Does the patient have a history of herpes labialis? All patients should be treated with prophylactic antiviral medication before ablative laser skin resurfacing in the perioral region, because reactivation and/or dissemination of prior herpes simplex infection can occur. The de-epithelialized skin is also particularly susceptible to primary inoculation by herpes simplex virus.
- Does the patient have an immunologic deficiency or autoimmune disease? Intact immunologic function and collagen repair mechanisms are necessary to optimize the tissue healing response due to the prolonged recovery associated with ablative resurfacing.
- Is the patient taking any medications that are contraindicated? Concomitant isotretinoin use could potentially lead to an increased risk of postoperative hypertrophic scar formation due to its detrimental effect on wound healing and collagenesis. A safe interval between the use of oral retinoids and ablative laser skin resurfacing is difficult to determine; however, most advocate a delay in treatment for at least 6 mo after discontinuation of the drug.
- Does the patient have a tendency to form hypertrophic scars or keloids? Patients with a propensity to scar will be at greater risk of scar formation after laser skin resurfacing, independent of the laser's selectivity and the operator's expertise.
- Does the patient have realistic expectations of the procedure and will he or she adhere to postoperative instructions? Those who cannot physically or emotionally handle the prolonged postoperative course should be dissuaded from pursuing ablative laser skin resurfacing procedures.

(skin phototype I or II), rhytides and other elements of photodamage that are amenable to treatment with an ablative resurfacing laser, and realistic expectations of the treatment.[3] Adequate preoperative patient evaluation and education are essential to optimize the clinical outcome (Table 252-1). Proper patient selection is paramount, because ablative laser resurfacing can be complicated by a prolonged postoperative recovery, pigmentary alterations, or unexpected scarring. The patient's emotional ability to tolerate an extended convalescence is an important factor in determining the most appropriate choice of laser. Although carbon dioxide (CO_2) or modulated erbium:yttrium-aluminum-garnet (Er:YAG) lasers produce the most dramatic clinical results, some patients may be unable to tolerate the intensive recovery period that is required. For patients either unable or unwilling to tolerate extended postoperative healing, a short-pulsed Er:YAG laser or non-ablative laser procedure may be a more suitable choice (see also Chap. 240).

Currently no consensus exists among laser experts regarding the most appropriate preoperative regimen for ablative laser skin resurfacing patients. The use of topical retinoic acid compounds, hydroquinone bleaching agents, or α-hydroxy acids for several weeks before ablative cutaneous resurfacing has been touted as a means of speeding recovery and decreasing the incidence of postinflammatory hyperpigmentation.[4] Topical tretinoin enhances penetration of chemicals through the skin and has been shown to accelerate postoperative re-epithelialization after dermabrasion or deep chemical peels.[5] Because ablative laser–induced wounds are intrinsically different from those created by physically destructive methods, however, laser skin penetration is not typically affected by the topical application of any of these medications.[4,6]

Due to the moist, de-epithelialized state of ablative laser–resurfaced skin and the possibility of bacterial contamination and overgrowth, many laser surgeons advocate oral antibiotic prophylaxis. This practice remains controversial, however, due to the findings of a controlled study that demonstrated no significant change in post–laser resurfacing infection rate in patients treated with prophylactic antibiotics.[7]

Equipment (See also Chap. 240)

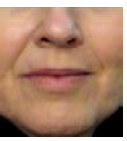
CARBON DIOXIDE LASER The first system developed for cutaneous laser resurfacing was the CO_2 laser, which was approved by the U.S. Food and Drug Administration in 1996. The earliest systems were continuous-wave CO_2 lasers, which were effective for gross lesional destruction.[8,9] However, these systems could not reliably ablate fine layers of tissue because of their prolonged tissue-dwell times, and they produced unacceptably high rates of scarring and dyspigmentation.[10–12] With the subsequent development of high-energy pulsed lasers, it became possible to safely apply higher energy densities with exposure times that were shorter than the thermal relaxation time of water-containing tissue, which lowered the risk of thermal injury to surrounding non-targeted tissue.[3,13,14]

Two of the first high-energy pulsed-laser systems developed were the UltraPulse 5000 and Silk-Touch lasers (Lumenis Corp., Yokeam, Israel). The UltraPulse emits individual CO_2 pulses (ranging from 600 microseconds to 1 millisecond) with peak energy densities of 500 mJ, whereas the SilkTouch is a continuous-wave CO_2 system with a microprocessor scanner that continuously moves the laser beam so that light does not dwell on any one area for more than 1 millisecond. The peak fluences delivered per pulse or scan range from 4 to 5 J/cm^2, which are the energy densities necessary for complete tissue vaporization.[10,15–17] Studies with these and other pulsed and scanned CO_2 laser systems have shown that after a typical skin resurfacing procedure, water-containing tissue is vaporized to a depth of approximately 20 to 60 μm, which produces a zone of thermal damage ranging from 20 to 150 μm.[10,16,18–20]

ERBIUM:YTTRIUM-ALUMINUM-GARNET LASER The short-pulsed Er:YAG laser was approved by the U.S. Food and Drug Administration in 1996 for use in cutaneous resurfacing. It was introduced as an alternative to the CO_2 laser for skin resurfacing in an attempt to minimize the recovery period and limit side effects while maintaining clinical benefit. The Er:YAG laser is a more precise ablative tool than is the CO_2 laser and emits 2940-nm light that corresponds to the 3000-nm absorption peak of water. The absorption coefficient of Er:YAG light is 12,800 cm^{-1} (compared with 800 cm^{-1} for that of the CO_2 laser), which makes it 12 to 18 times more efficiently absorbed by water-containing tissue than is the light of the CO_2 laser.[21] The pulse duration (mean of 250 microseconds) is also much shorter than that of the CO_2 laser;

this results in decreased thermal diffusion, less effective hemostasis, and increased intraoperative bleeding, which often hampers deeper dermal treatment. In addition, because of limited thermal skin injury, the amount of collagen contraction is also reduced with Er:YAG treatment compared with that observed with CO_2 laser irradiation.[15,22]

The Er:YAG laser's efficient rate of absorption, short exposure duration, and direct relationship between fluence delivered and amount of tissue ablated leads to 2 to 4 μm of tissue vaporization per J/cm^2, which produces a shallow level of tissue ablation. Much narrower zones of thermal necrosis, averaging only 20 to 50 μm, are therefore produced.[21,23–25]



Conditions amenable to short-pulsed Er:YAG laser resurfacing include superficial epidermal or dermal lesions, mild photodamage, and subtle dyspigmentation. The major advantage of short-pulsed Er:YAG laser treatment is the shorter recovery period after therapy. Re-epithelialization is completed within an average of 5.5 days, compared with 8.5 days for multi-pass CO_2 procedures.[16,23] Postoperative pain and duration of erythema are reduced after short-pulsed Er:YAG laser resurfacing, with postoperative erythema resolving within 3 to 4 weeks. Because there is less thermal injury and trauma to the skin, the risk of pigmentary disturbance is also decreased, which makes the short-pulsed Er:YAG laser a good alternative in treating patients with darker skin phototypes.[3,26] The major disadvantages of the short-pulsed Er:YAG laser are its limited ability to effect significant collagen shrinkage and its failure to induce new and continued collagen formation postoperatively.[3,23,27] Because of this, the final clinical result is often less impressive than that produced by CO_2 laser skin resurfacing for deeper rhytides.

To address the limitations of the short-pulsed Er:YAG laser, modulated Er:YAG lasers systems were developed to improve hemostasis and increase the amount of collagen remodeling produced.[28] The Er:YAG–CO_2 hybrid laser system delivers both ablative Er:YAG and coagulative CO_2 laser pulses. The Er:YAG component generates fluences of up to 28 J/cm^2 with a 350-microsecond pulse duration, and excellent hemostasis is provided by the CO_2 component, which can be programmed to deliver 1- to 100-millisecond pulses at 1 to 10 W of power. Zones of thermal necrosis measuring as much as 50 μm have been observed depending on the treatment parameters used, and significant increase in collagen thickness has been noted 3 months after four passes with a device using this hybrid technology.[29] Another modulated Er:YAG device is a dual-mode Er:YAG laser that emits a combination of short (200- to 300-microsecond) pulses and long coagulative pulses to achieve tissue ablation depths of up to 200 μm per pass.[28,29] The desired depth of ablation and coagulation can be programmed by the laser surgeon using a touch-screen control panel. Several investigators have studied the histologic effects of dual-mode Er:YAG laser resurfacing and found a close correlation between the programmed and actual measured depths of ablation.[30,31] The actual zones of thermal injury correlate well with the first-pass parameters, with decreasing coagulative efficiency on subsequent passes. The variable-pulsed Er:YAG laser system delivers pulse durations ranging from 500 microseconds to 10 milliseconds. Shorter pulse durations are used for tissue ablation and longer pulses are used to effect coagulation and zones of thermal injury as with the CO_2 laser.[32–34]

Anesthesia

Most ablative laser resurfacing is performed as an outpatient procedure in an ambulatory surgery facility. Regional laser skin resurfacing (perioral or periorbital) can be performed with local anesthesia with no additional analgesia. However, full-face laser skin resurfacing often requires additional analgesia, including one or more of the following: oral sedation, nerve blocks, tumescent anesthesia, topical anesthetic creams, and intravenous (IV) sedation. Topical anesthesia protocols have been outlined using either lidocaine cream application for several hours before CO_2 laser resurfacing to enhance tissue hydration and anesthetic penetration[35] or a cream-based formulation that dries to a flexible membrane, which is peeled away from the skin before laser irradiation.[36]

Despite their obvious advantages, these topical regimens are frequently more time consuming and less uniformly effective. For this reason, many dermasurgeons prefer a deeper form of anesthesia for full-face ablative laser procedures, using regional nerve blockade and IV sedation to provide more complete anxiolysis, amnesia, and sedation.[37] If IV sedation or general anesthesia is used, special precautions must be taken in the presence of oxygen. CO_2 lasers have been reported to be the source of operating room fires, so care must be taken to eliminate exposure to flammable objects. A smoke evacuator must be used to avoid exposure to the laser plume.

Technique

CARBON DIOXIDE LASER SKIN RESURFACING The objective of ablative laser skin resurfacing is to vaporize tissue to the level of the papillary dermis. Limiting the depth of penetration decreases the risk of scarring and permanent pigmentary alteration. When choosing treatment parameters, the surgeon must consider such factors as the anatomic site to be resurfaced, the skin phototype of the patient, and previous skin treatments delivered.[15,38] In general, thinner skin (e.g., periorbital) requires fewer laser passes, and laser resurfacing of non-facial skin (e.g., neck, chest) should be avoided due to the relative paucity of pilosebaceous units in these areas.[38] To reduce the risk of excessive thermal injury during multi-pass procedures, partially desiccated tissue should be removed manually with wet gauze after each laser pass to expose the underlying dermis.[39]

The depth of ablation is directly correlated with the number of passes performed and usually is restricted to the epidermis and upper papillary dermis.[40] However, stacking laser pulses by treating an area with multiple passes in rapid succession or by using a high-overlap setting on a scanning device leads to excessive thermal injury to the skin with subsequent increased risk of scarring.[39,41] An ablative plateau is reached, which results in less effective tissue ablation and increased tissue heating. This effect is most likely caused by reduced tissue water content after initial desiccation, with reduced selective absorption of energy.[39] The avoidance of pulse stacking and incomplete removal of partially desiccated tissue is paramount to prevention of excessive thermal accumulation with the use of any laser system.

In an attempt to address many of the difficulties associated with the use of multi-pass CO_2 laser skin resurfacing, refinements in surgical technique have been developed. A minimally traumatic single-pass CO_2 laser resurfacing procedure has been described that results in faster re-epithelialization and a more improved side effect profile than have been reported with the multiple-pass technique.[42] Partially desiccated tissue is not removed (as is standard with multi-pass procedures); rather, the lased skin is left intact to serve as a biologic

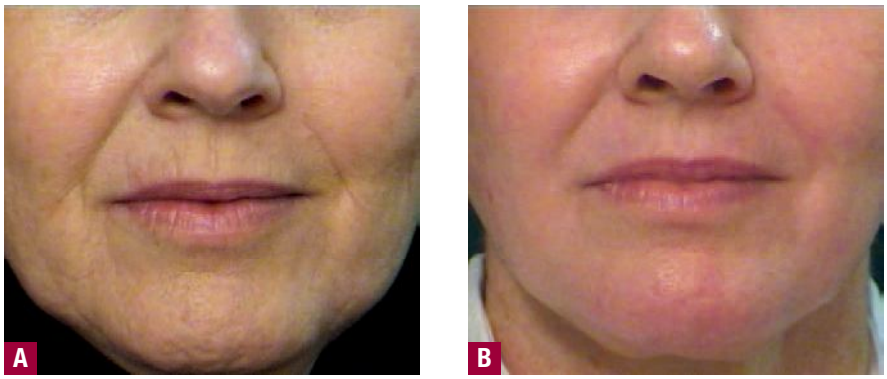
wound dressing. Additional laser passes can then be applied focally only in areas of more extensive involvement to limit unnecessary thermal and mechanical trauma to less involved skin. Subsequent reports have substantiated the improved side effect profile of this less aggressive procedure.[43–45]

ERBIUM:YTTRIUM-ALUMINUM-GARNET LASER SKIN RESURFACING The short-pulsed Er:YAG laser fluences used most often range from 5 to 15 J/cm^2, depending on the degree of photodamage and anatomic location. On irradiation, laser-induced ejection of desiccated tissue from the target site produces a distinctive popping sound. Thermal energy is confined to the selected tissue, with minimal collateral thermal damage. Because little tissue necrosis is produced with each pass of the laser, manual removal of desiccated tissue is often unnecessary. The ablation depth with the short-pulsed Er:YAG laser does not diminish with successive passes because the amount of thermal necrosis is nominal. It takes three to four times as many passes with the short-pulsed Er:YAG laser to achieve similar depths of penetration as with one pass of the CO_2 laser at typical treatment parameter settings.[3,15] To ablate the entire epidermis with the short-pulsed Er:YAG laser using a fluence of 5 J/cm^2, at least two or three passes must be carried out, which increases the possibility of uneven tissue penetration. Treatment of deeper dermal lesions or areas of the face with extensive photodamage and dermal elastosis may require up to 9 or 10 passes of the short-pulsed Er:YAG laser, whereas the CO_2 laser would effect similar levels of tissue ablation in 2 or 3 passes.[10,16,21]

Pinpoint bleeding caused by inadequate hemostasis and tissue color change after multiple short-pulse Er:YAG passes can impede adequate clinical assessment of wound depth. Irradiated areas whiten immediately after treatment and then quickly fade. These factors render it more difficult to determine treatment endpoints and, thus, require extensive knowledge of laser-tissue interaction on the part of the operator. Modified Er:YAG ablative laser resurfacing provides better hemostasis and visualization of the treatment area because of the added thermal effects on the tissue.[46]

Outcomes Assessment

The clinical and histologic benefits of cutaneous laser resurfacing are numerous.



▲ **FIGURE 252-1** Facial photodamage and rhytides before (**A**) and several months after (**B**) ablative CO_2 laser skin resurfacing.

With the CO_2 laser, most studies have shown at least a 50 percent improvement over baseline in overall skin tone and wrinkle severity (Fig. 252-1).[14,47–51] The greatest advantages associated with CO_2 laser skin resurfacing are the excellent tissue contraction, hemostasis, prolonged neocollagenesis, and collagen remodeling that result. Histologic examination of laser-treated skin demonstrates replacement of epidermal cellular atypia and dysplasia with normal, healthy epidermal cells from adjacent follicular adnexal structures.[10,19] The most profound effects occur in the papillary dermis, where coagulation of disorganized masses of actinically induced elastotic material are replaced with normal compact collagen bundles arranged in parallel to the skin's surface.[52,53] Immediately after CO_2 laser treatment, a normal inflammatory response is initiated, with granulation tissue formation, neovascularization, and increased production of macrophages and fibroblasts.[19]

Persistent collagen shrinkage and dermal remodeling are responsible for much of the continued clinical benefits observed after CO_2 resurfacing and are influenced by several factors.[54,55] Thermal effects of laser irradiation of skin produce collagen fiber contraction at temperatures ranging from 55°C to 62°C (131°F to 143.6°F) through disruption of interpeptide bonds, which results in a conformational change to the collagen's basic triple-helical structure.[56,57] The collagen molecule is thereby shortened to approximately one-third of its normal length. Collagen fibers with laser-induced shrinkage may act as the contracted scaffold for neocollagenesis, which leads to subsequent production of the newly shortened form. In turn, fibroblasts that migrate into laser wounds after resurfacing may upregulate the expression of immune-modulating factors that serve to enhance continued collagen shrinkage.[58]

Because the modulated Er:YAG lasers were developed to produce a greater thermal effect and tissue contraction than did their short-pulsed predecessors, investigators compared collagen tightening induced by the CO_2 laser with that of the CO_2–Er:YAG hybrid laser system.[32] Intraoperative contraction of approximately 43 percent was produced after three passes of the CO_2 laser, compared with 12 percent contraction after Er:YAG irradiation. At 4 weeks, however, the CO_2 laser– and Er:YAG laser–treated sites were contracted to the same degree, which highlights the different mechanisms of tissue tightening observed after laser treatment. Immediate thermal-induced collagen tightening was the predominant response seen after CO_2 irradiation, whereas modulated Er:YAG laser resurfacing did not produce immediate intraoperative contraction but instead induced slow collagen tightening.[28,32]

Side Effects and Complications

Side effects associated with CO_2 laser skin resurfacing vary and are related to the expertise of the laser surgeon, the body area treated, and the skin phototype of the patient (Table 252-2). Certain tissue reactions, such as erythema and edema, are expected in the immediate postoperative period and are not considered adverse events. Erythema can be intense and may persist for several months after the procedure. The degree of erythema correlates directly with the depth of ablation and the number of laser passes performed.[3,59] It may also be aggravated by underlying rosacea or dermatitis. Postoperative erythema resolves spontaneously but can be reduced with the application of topi-

cal ascorbic acid, which may serve to decrease the degree of inflammation.[60,61] It should not be used for at least 4 weeks after the procedure to avoid irritation. Likewise, other topical agents such as retinoic acid derivatives, glycolic acid, fragrance- or chemical-containing cosmetics, and sunscreens should be strictly avoided in the early postoperative period until substantial healing has occurred.[59]

Mild side effects of laser skin resurfacing include milia formation and acne exacerbation, which may be caused by the use of occlusive dressings and ointments used during the postoperative period, particularly in patients who are acne prone.[38,41,59,62] Milia and acne usually resolve spontaneously as healing progresses and the application of thick emollient creams and occlusive dressings ceases. Oral antibiotics may be prescribed for acne flares that do not respond to topical preparations.[51,59,62] Contact dermatitis, either irritant or allergic, can also develop from various topical medications, soaps, and moisturizers used postoperatively. Most of these reactions are irritant in nature due to decreased barrier function of the newly resurfaced skin.[59,63]

Wound infections associated with ablative laser resurfacing include *Staphylococcus* and *Pseudomonas* infections and cutaneous candidiasis and should be treated aggressively with an appropriate systemic antibiotic or antifungal agent.[64] The most common infectious complication is a reactivation of labial herpes simplex virus (HSV) infection, most likely caused by the thermal tissue injury and epidermal disruption produced by the laser.[41,59] All patients undergoing full-face or perioral ablative resurfacing should receive antiviral prophylaxis even if they report no history of HSV infection. After CO_2 resurfacing, approximately 7 percent of patients develop a localized or disseminated form of HSV infection.[59] These infections develop within the first postoperative week and can present as erosions without intact vesicles because of the denuded condition of newly lased skin. Even with appropriate prophylaxis, a herpetic outbreak still can occur in upward of 10 percent of patients and must be treated aggressively.[15] Oral antiviral agents such as acyclovir, famciclovir, and valacyclovir are effective agents against HSV infection, although IV therapy may be required in severe (disseminated) cases. Patients should begin prophylaxis by the day of surgery and continue it for 7 to 10 days postoperatively.[65]

Hyperpigmentation is one of the more common side effects of cutaneous laser resurfacing and occurs to some degree in all patients with darker skin tones.[58,64] The reaction is transient, but its resolution can be hastened with the postoperative use of a variety of topical agents, including hydroquinone and retinoic, azelaic, and glycolic acid. Regular sunscreen use is also important during the healing process to prevent further skin darkening. Postoperative hypopigmentation is often not observed for several months and is particularly difficult because of its tendency to be intractable to treatment. The use of an excimer laser or topical photochemotherapy to stimulate repigmentation has proven successful in some patients.[66,67]

The most severe complications associated with ablative cutaneous laser resurfacing are hypertrophic scars and ectropion formation.[40,58] Although the risk of scarring has been significantly reduced with the newer pulsed systems, inadvertent pulse stacking or scan overlapping as well as incomplete removal of desiccated tissue between laser passes can cause excessive thermal injury that could increase the development of fibrosis. Focal areas of bright erythema with pruritus, particularly along the mandible, may signal impending scar formation.[37,64,65] Potent topical corticosteroid preparations should be applied to decrease the inflammatory response. A pulsed dye laser also can be used to improve the appearance and symptoms of laser-induced burn scars.[65]

Ectropion of the lower eyelid after periorbital laser skin resurfacing is rarely seen but, if encountered, usually requires surgical correction.[37] It is more likely to occur in patients who have had previous lower blepharoplasty or other surgical manipulation of the periorbital region. Preoperative examination is essential to determine eyelid laxity and skin elasticity. If the infraorbital skin does not return briskly to its normal resting position after a manual downward pull (snap test), then ablative laser resurfacing near the lower eyelid margin should be avoided. In general, lower fluences and fewer laser passes should be applied in the periorbital area to decrease the risk of lid eversion.

Side effects and complications after Er:YAG laser resurfacing are similar to those observed after CO_2 laser skin resurfacing, but they differ in duration, incidence, and severity.[68–70] Although greater postoperative erythema is seen after modulated Er:YAG laser treatment than is usually produced with a short-pulsed Er:YAG system, the side effect profile and recovery period after modulated Er:YAG laser skin resurfacing remain more favorable than after multi-pass CO_2 laser treatment. In an extended evaluation of 50 patients, investigators reported complete re-epithelialization in an average of 5 days after dual-mode Er:YAG laser skin resurfacing, with only three patients experiencing prolonged erythema beyond 4 weeks.[29] In a split-face comparison of 16 patients after pulsed CO_2 and variable-pulsed Er:YAG laser skin resurfacing, other investigators reported decreased erythema, less edema, and faster healing on the Er:YAG laser–treated facial half.[34]

Post-inflammatory hyperpigmentation is not uncommon after any cutaneous laser resurfacing procedure. Although hyperpigmentation after modulated Er:YAG laser skin resurfacing (mean duration, 10.4 weeks) can last longer than after treatment with a short-pulsed Er:YAG laser, it is not as persistent as that observed after multiple-pass CO_2 laser resurfacing (mean duration, 16 weeks).[29] However, when the most current techniques in ablative cutaneous laser resurfacing are compared (single-pass CO_2 versus multiple-pass, long-pulsed Er:YAG laser skin resurfacing), postoperative healing times and complication profiles are comparable, even in patients with darker skin phototypes. In a retrospective review and analysis of 100 consecutively treated patients, investigators found that average time to re-epithelialization was 5.5 days with single-pass CO_2 and 5.1 days with long-pulsed Er:YAG laser resurfacing.[45] Postop-

erative erythema was observed in all patients, lasting an average of 4.5 weeks after single-pass CO_2 laser treatment and 3.6 weeks after long-pulsed Er:YAG laser treatment. Hyperpigmentation was seen in 46 percent of patients treated with a single pass of the CO_2 laser and 42 percent of patients treated with the long-pulsed Er:YAG laser (average duration, 12.7 weeks and 11.4 weeks, respectively).

Postoperative Care and Patient Instructions

Proper wound care during the immediately postoperative period is vital to the successful recovery of ablative laser–resurfaced skin. During the re-epithelialization process, an open or closed wound treatment technique can be prescribed. Partial-thickness cutaneous wounds heal more efficiently and with a much reduced risk of scarring when maintained in a moist environment, because the presence of a dry crust or scab impedes keratinocyte migration.[71] Although there is consensus on this principle among laser surgeons, disagreement exists regarding the optimal dressing for the laser-ablated wound. The "open" technique involves frequent application of thick healing ointment to the de-epithelialized skin surface, whereas occlusive or semi-occlusive dressings are placed directly on the lased skin in the "closed" technique. Although the open technique facilitates wound visualization, the closed technique requires less patient involvement and may also decrease postoperative pain. Proposed advantages of closed dressings include increased patient comfort, decreased erythema and edema, increased rate of re-epithelialization, and decreased patient involvement in wound management[71,72]; however, additional expense and a higher risk of infection have been associated with their use.[3,62,64]

In addition to the prescribed wound care, ice pack application and the administration of anti-inflammatory medications should be carried out during this time. Furthermore, pain medication during the first few postoperative days is particularly important for patients undergoing ablative laser resurfacing.

FRACTIONAL RESURFACING

A novel approach in skin resurfacing termed *fractional photothermolysis* has been developed to address the shortcomings associated with cutaneous laser resurfacing using the currently available lasers and light sources.[73] Although dramatic clinical improvement can be achieved with traditional ablative laser resurfacing, patients are often hesitant to pursue this treatment option because of the extended postoperative recovery period and inherent risks of the procedure. Non-ablative lasers and light sources, on the other hand, have demonstrated modest efficacy in the non-invasive treatment of mild facial rhytides and atrophic scarring with minimal side effects, but require multiple treatments with delayed and often inconsistent clinical results (see Chap. 253).

Fractional photothermolysis involves the creation of microscopic thermal wounds with sparing of the surrounding tissue.[74] Fractional resurfacing is performed using a 1550-nm erbium fiber laser (Fraxel, Reliant Technologies, Mountain View, CA) that targets water-containing tissue to effect photocoagulation of narrow columns of skin (microscopic thermal zones) at depths of 200 to 500 μm and spaced at 200- to 300-μm intervals (see Chap. 240). Histologic evaluation of skin immediately after treatment reveals thermal injury sharply confined to these narrow columns extending from the epidermis to the mid-dermis.[74] Microscopic epidermal necrotic debris exfoliates over the next several days, producing a bronzed appearance to the skin.[75] The wound healing response differs from the response after the use of ablative techniques because the epidermal tissue that is spared between thermal zones contains viable transient amplifying cells capable of rapid re-epithelialization. Furthermore, because the stratum corneum has a low water content, it remains intact immediately after treatment. Therefore, the wound created by fractional resurfacing is unique—not simply that of an ablative laser used to make "holes" in the skin. In addition, fractional resurfacing can provide an advantage over purely non-ablative laser treatments due to the gradual exfoliation of the epidermis with resultant improvement in superficial dyspigmentation (Fig. 252-2). Because only a fraction of the skin is treated during a single session, a series of fractional resurfacing treatments is required for the best clinical improvement.

Investigators have shown fractional resurfacing to be a safe and effective treatment for a variety of indications, including photodamage, atrophic scars, and dyspigmentation.[76–80] Side effects of fractional resurfacing are typically mild and transient and include erythema, periocular edema, and a slight darkening of the skin (bronzing) as the microscopic epidermal necrotic debris desquamates. Erosions are uncommon and can be managed by liberal application of a healing ointment or plain petrolatum with cool, wet compresses every 2 to 3 hours. To date, permanent pigmentary alteration and scarring have not been reported. However, when an aggressive treatment protocol with a high density of microscopic thermal zones is used, the risk of visible epidermal ablation, along with the side effects associated with ablative laser procedures, is increased. Additional research is ongoing to determine optimal treatment parameters and the long-term benefits and sequelae of fractional resurfacing.

CHEMICAL PEEL

The controlled application of one or more exfoliating agents to the skin is a highly efficient and versatile way to improve photodamaged skin. The level of injury and the depth of penetration into the skin determine the classification as a superficial, medium, or deep chemical peel (Table 252-3). Although superficial peeling agents aimed at removing all or part of the epidermis are useful for su-

▲ **FIGURE 252-2** Facial photodamage and rhytides before (**A**) and 9 months after (**B**) a series of fractional laser treatments.

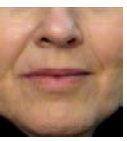

TABLE 252-3
Chemical Peel Classification

TYPE	DEPTH OF PENETRATION
Superficial	Epidermis to upper papillary dermis
Medium	Papillary dermis to upper reticular dermis
Deep	Mid-reticular dermis

perficial dyspigmentation, acne, and solar lentigines, they have minimal effect on rhytides and require multiple treatments for the best clinical results (Table 252-4). More complete skin rejuvenation requires the application of a medium or deep chemoexfoliant.[81,82]

Medium-Depth Peels

Medium-depth chemical peels are defined as those causing injury to the skin at or through the papillary dermis (Table 252-5).[83–85] Trichloroacetic acid (TCA) at concentrations of 35 percent to 50 percent is the classic agent in this category. Because 50 percent TCA may produce an unpredictable response with subsequent hypopigmentation and scarring, the combination of a superficial peeling agent such as Jessner's solution or glycolic acid before the application of 35 percent TCA is advocated to achieve more consistent results with an increased margin of safety (Fig. 252-3).[86–88]

The Jessner's solution–TCA peel is performed after thorough cleansing of the treatment area with soap followed by degreasing with an alcohol and acetone solution. Jessner's solution (Table 252-6) is applied in one or two coats to achieve a pale, uniform frost. The TCA is then applied evenly over the skin surface. Those portions of the face with a high concentration of sebaceous glands (T-zone) may receive additional acid in a second application. The observed white frost indicates protein denaturation of keratin and completion of the chemical peel reaction. Cool water compresses and emollient creams are then applied for symptomatic relief. Postoperatively, erythema, edema, and desquamation are expected, with increased severity of side effects noted with the higher acid concentrations and larger number of applications.

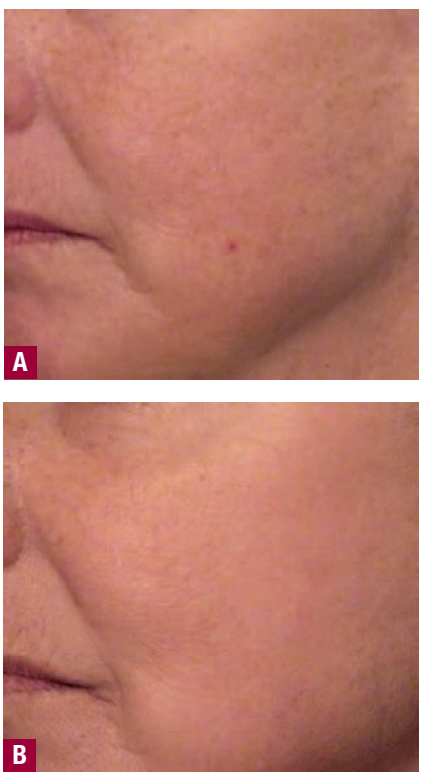
- Solid CO_2 and 35% TCA
- Jessner's solution and 35% TCA
- 70% Glycolic acid and 35% TCA
- 88% Phenol

Deep Chemical Peels

Phenol is a keratocoagulant that is the only deep peeling agent widely used. Application of phenol, as described by Baker and Gordon in the 1960s, causes wounding that penetrates to the mid-reticular dermis.[88–91] Baker's formula (Table 252-7) should be freshly prepared and stirred continuously before and during the procedure to ensure even application of the solution. For a full-face phenol peel, regional nerve blocks in combination with analgesics such as propofol (Diprivan) and anxiolytics such as midazolam can be used. Because phenol is partially detoxified in the liver and excreted by the kidney, hydration with lactated Ringer's solution before and during the treatment is warranted to limit toxicity. Furthermore, because phenol is cardiotoxic, close patient monitoring is necessary during and after the procedure.[92]



▲ **FIGURE 252-3** Facial dyspigmentation before (**A**) and 6 months after (**B**) treatment with a 30 percent trichloroacetic acid peel.

TABLE 252-6
Jessner's Solution

- Lactic acid 14 g
- Salicylic acid 14 g
- Resorcinol 14 g
- Ethanol 95% in quantity sufficient to yield 100 mL

After degreasing the skin with hexachlorophene (Septisol), fresh Baker's solution is applied systematically over aesthetic units using cotton-tipped applicators, with time (10 to 15 minutes) allowed to elapse between treating different regions to minimize absorption, which can lead to systemic toxicity. The solution can be feathered beyond the margins of the treated areas to reduce the line of demarcation between treated and untreated skin.

Postoperatively, an open wound care technique has been favored over a closed dressing due to the lower risk of infection and scarring and speedier re-epithelialization.[92,93] Petrolatum is applied liberally to the wound until re-epithelialization is complete, usually within 7 to 10 days.

Side Effects and Complications

The risk of side effects and complications (Table 252-8) increases proportionately with the depth of the chemical peeling agent. Superficial peels are associated with the lowest risk of adverse reactions, whereas medium-depth peels can cause dyspigmentation and, rarely, scarring. Phenol peels are further associated with hepatic, renal, and cardiac toxicity.

DERMABRASION

Modern techniques for dermabrasion were initially described by Paul Kurtin in 1953.[93] Dermabrasion involves the mechanical removal of the epidermis and dermis in a controlled fashion. Indica-

tions for treatment include rhytides, facial scars, rhinophyma, epidermal nevi, syringoma, and many other benign skin conditions.[94–97] Dermabrasion is highly operator dependent, and the practitioner must have extensive knowledge and experience to obtain excellent results while maintaining high levels of safety. The use of dermabrasion, except for spot treatment of specific lesions or scars, has been largely supplanted by treatment with a variety of ablative lasers.

Before dermabrasion is performed, a thorough patient consultation and evaluation is necessary to identify recent isotretinoin use, abnormal scarring tendency, prior treatments to the area, drug allergies, clotting or pigmentary disorders, and koebnerizing skin conditions. Preoperative antiviral prophylaxis is warranted for perioral or full-face procedures.[98,99]

Dermabrasion is performed using a wire brush or diamond fraise powered by a hand engine.[94] Fraises are available in multiple sizes, shapes, and degrees of coarseness. Pear-shaped fraises and cones are most often used around the nose and oral commissure, whereas wheels are used over flat, broad skin surfaces.[98] In general, diamond fraises offer a greater margin of safety than does the wire brush type, which removes a greater amount of tissue (Fig. 252-4).

The form of anesthesia used for dermabrasion varies depending on the surgeon, the area to be dermabraded, the desired depth of treatment, and the patient's pain tolerance. The use of liquid refrigerants can be problematic because of their potential for excessive skin injury; however, cryoanesthesia has the advantage of providing a firm surface on which to treat. Tumescent anesthesia with 0.05 percent to 0.1 percent lidocaine solution (with or without the concomitant use of nerve blocks and oral anxiolytics) is an effective form of anesthesia for full-face dermabrasion. A volume of 250 to 350 mL is typically adequate for the full face.[98]

Dermabrasion is performed in the operating room under strict universal precautions due to the risk of aerosolization of viral particles. The area to be dermabraded is stabilized manually without distortion of the normal skin contour. Some operators use an aerosol refrigerant to stiffen the skin surface to enhance depth control. The device is pulled rather than pushed over the cutaneous surface, which itself is positioned parallel to the floor. The dermabrasion is performed to the desired depth by closely monitoring the skin surface appearance. Decreased skin pigmentation is observed on epidermal removal, followed by punctate, pinpoint bleeding when the papillary dermis has been reached. The level of the reticular dermis is signaled by a whitish yellow appearance with fewer blood vessels. The goal of dermabrasion is to penetrate to the level of the dermis while avoiding the lower dermis and subcutaneous layer to reduce the risk of scarring. Feathering at the margins of the treatment area can soften the transition between treated and untreated skin.

On completion of a full-face dermabrasion, a dilute lidocaine and epinephrine solution can be used topically to soothe the treated area and improve hemostasis. The use of various biologic and nonbiologic sterile dressings has been advocated, but the choice is determined by the preference of the surgeon.[99] Depending on the total area and depth of dermabrasion, re-epithelialization is typically complete within 7 to 10 days. Meticulous wound care and close observation during the period of re-epithelialization permits the early detection of and intervention for such potential complications as herpetic, bacterial, and fungal infections. Side effects and complications after dermabrasion are similar to those seen after an ablative laser skin resurfacing procedure (see Table 252-2); however, the incidence of permanent hypopigmentation is markedly higher after dermabrasion (20 percent to 30 percent) than after ablative laser treatment.

CHAPTER 253

Cosmetic Applications of Non-Ablative Lasers and Other Light Devices

Anne M. Chapas
Roy G. Geronemus

Over the last 40 years, the explosive advancement of laser technology has revolutionized the treatment of numerous skin conditions. The principle of selective photothermolysis set forth in 1983 by Anderson and Parrish[1] has formed the basis for the development of lasers that selectively target and destroy tissues containing water, hemoglobin, and pigment. Lasers showing such selective action were first applied to improve various potentially disfiguring medical conditions such as port-wine stains, hemangiomas, and pigmented birthmarks. More recently, these same principles have been implemented in an effort to improve the cosmetic appearance of normal and aging skin. Because laser treatments target all aspects of photoaging, from ameliorating the appearance of fine and deep rhytides to softening skin texture and improving pigmentation and skin laxity, they are becoming an indispensable tool in the armamentarium of the cosmetic dermatologist. An understanding of the benefits and limitations of each laser technique and the expectations and lifestyle of the individual patient allow the practitioner to achieve the most satisfying cosmetic results.

NON-ABLATIVE SKIN REJUVENATION

Skin rejuvenation by laser was originally performed with devices that resulted in the destruction or ablation of the epidermis and elements of the dermis. The demand for less invasive procedures with shorter recovery times than those of traditional ablative laser resurfacing has led to the development of non-ablative laser surgery. Many of these systems emit light in the infra-red portion of the electromagnetic spectrum (1000 to 1500 nm), which is absorbed by water in deeper tissues while leaving the epidermis intact. This type of dermal wounding stimulates new collagen and elastin formation, which can improve the appearance of skin with mild to moderate photodamage. In general, the results are not comparable to those achieved with ablative lasers, but many patients are willing to accept more modest clinical improvements in exchange for fewer side effects and shorter recovery times.

Patient Selection

Proper patient selection is the key to successful non-ablative laser resurfacing (see Chap. 252 for ablative laser procedures). Patients with realistic expectations who have mildly to moderately photodamaged skin are the best candidates for non-ablative procedures. Results from non-ablative laser treatments are generally gradual and progressive, with textural irregularities and pigment irregularities improving more than rhytides. Patients who seek immediate dramatic results are likely to be disappointed with the overall clinical outcome.

Risks and Precautions

As with ablative laser resurfacing, the heat produced by non-ablative systems can reactivate prior herpes simplex infections (Table 253-1). Patients with a strong history of herpes labialis should receive prophylactic oral antiviral medication before treatment. Although non-ablative laser procedures have an extremely low risk of scarring, these risks are increased in patients who have received isotretinoin in the previous year. Therefore, these patients should not undergo non-ablative resurfacing. Finally, patients with darker skin phototypes may develop a temporary post-inflammatory hyperpigmentation after non-ablative laser treatment.

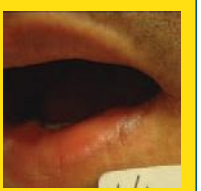
Patient Positioning

Non-ablative laser resurfacing can be performed in the physician's office, with both the patient and clinical personnel wearing proper eye protection.

TABLE 253-1
Non-Ablative Resurfacing: Risks and Precautions

- Contraindicated in patient with prior isotretinoin treatment
- May lead to post-inflammatory hyperpigmentation
- May cause reactivation of herpes simplex virus infection

COSMETIC APPLICATIONS OF NON-ABLATIVE LASERS AND OTHER LIGHT DEVICES AT A GLANCE



- A wide range of lasers and other light devices can be used to treat skin problems of cosmetic concern.
- Photorejuvenation can be achieved with non-ablative devices.
- Vascular and pigmented lesions benefit from treatment with lasers capable of selective photothermolysis.
- Patient selection and patient expectation are critical for optimum outcome.
- All safety precautions must be followed during treatment.

Equipment

Several visible-light lasers have been developed to target discrete chromophores to stimulate dermal remodeling (Table 253-2). One of the first approaches to photorejuvenation used pulsed dye lasers (PDL) emitting light at wavelengths of either 585 nm or 595 nm. The ability of PDL treatment to improve the appearance of hypertrophic scars, striae distensae, and acne scars suggests that PDL treatment stimulates new collagen formation. A small clinical study confirmed that a single treatment with a PDL (585 nm, 450 microseconds) in-

TABLE 253-2
Non-Ablative Resurfacing: Equipment

- Visible-light lasers: 585 nm, 595 nm, long-pulse 1064-nm neodymium:yttrium-aluminum-garnet, 1320 nm, 1450 nm, 1540-nm, erbium:glass, fractional photothermolysis
- Intense pulsed light devices
- Radiofrequency devices

duced clinical improvement in 75 percent to 90 percent of mild to moderate rhytides and 40 percent of moderate to severe rhytides.[2] Longer-wavelength lasers such as the 1064-nm Q-switched neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, the 1320-nm Nd:YAG laser, the 1450-nm diode laser, and 1540-nm erbium:glass laser have also been shown to induce dermal remodeling. Multiple treatments are necessary at 2- to 4-week intervals. The effects are often gradual due to ongoing collagen formation, which may occur up to 6 months after the last treatment.

Treatment with intense pulsed light (IPL) devices, which emit a broad, continuous spectrum of light from 515 nm to 1200 nm, has been shown to successfully rejuvenate photodamaged skin. Filters can be placed over the beam to eliminate the shorter wavelengths, which target hemoglobin and melanin, depending on the clinical application. Studies have shown that IPL treatment produces substantial clinical improvement in the dyspigmentation and telangiectasias that are associated with photoaging but only mild improvement in rhytides.[3]

In contrast to visible-light lasers creating large sheets of thermal damage, the lasers used for fractional photothermolysis are mid–infra-red devices that create columns of thermal injury deep into the dermis, similar to pixels in a digital photograph.[4] The epidermis rapidly heals around these columns of thermal damage, which stimulate progressive collagen remodeling. Treatments are generally scheduled at 1- to 4-week intervals for a total of three to six sessions. Photodamage of the face, neck, chest, and hands; acne scars (Fig. 253-1); striae distensae (Fig. 253-2); and melasma have all been shown to respond to fractional photothermolysis.

Several non-ablative devices that deliver energy deep into the dermis have been shown to cause skin tightening. The direct application of infra-red light, with pre-treatment and post-treatment contact cooling of the skin, has been shown to heat deep collagen to the point of contraction. In appropriate patients, this contraction results in a visible tightening of redundant skin. Skin tightening can also be achieved by the use of a radiofrequency device generating electric current, which produces heat through resistance in the dermis. Periorbital rhytides and middle and lower face laxity generally require one to three treatments at 4-week intervals, with tightening noted 1 to 3 months after the last treatment[5] (Fig. 253-3). A new infra-red device that emits light at 1100 to 1800 nm in multisecond cycles has also been shown to induce skin contraction.

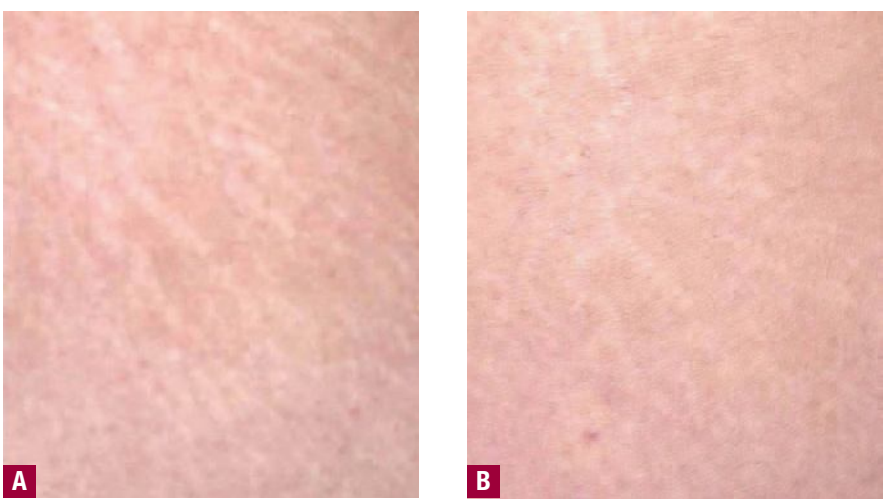
▲ **FIGURE 253-1** Acne scarring treated with fractional photothermolysis. **A.** Before treatment. **B.** After treatment.

Anesthesia

Non-ablative laser procedures are generally more easily tolerated than ablative procedures. The degree and type of anesthesia required depends on the patient's pain tolerance and the amount of heat energy generated by the device. A topical anesthetic such as lidocaine or a eutectic mixture of lidocaine and prilocaine applied 1 hour before the procedure is usually sufficient. Forced-air cooling can also make the procedure more tolerable. Higher-energy procedures such as fractional photothermolysis occasionally require nerve block, oral or intramuscular analgesics, and anxiolytics.

Technique

Non-ablative visible-light laser systems require different treatment parameters depending on the skin type and condition to be treated. To protect the epidermis, all of these devices are used in conjunction with a contact cooling handpiece or cryogen spray delivered several milliseconds before the laser pulse. IPL devices are used with various filters and at different energy levels depending on the desired treatment effect. A transparent water-based gel is used to protect the epidermis. Fractional photothermolysis is performed in the presence of forced-air cooling. Various density and energy settings are used.



▲ **FIGURE 253-2** Striae distensae treated with fractional photothermolysis. **A.** Before treatment. **B.** Three months after treatment.

▲ **FIGURE 253-3** Facial laxity treated with a monopolar radiofrequency device. **A.** Before treatment. **B.** Two months after treatment. **C.** Four months after treatment. **D.** Six months after treatment.

Finally, tightening procedures are performed by holding the handpiece in firm contact with the treated skin. Several investigators have shown that multiple passes at relatively low to medium energies are effective and more tolerable for patients than high-energy treatments.

Outcomes Assessment

Because non-ablative laser treatments stimulate collagen remodeling over several months, objective clinical improvements after a series of treatments may take weeks or months to be achieved. Reassurance by the physician as well as the use of pre-treatment photographs may help patients better appreciate their progress. Setting realistic goals and targeting the aspects of photoaging that are important to the patient will also yield a more favorable outcome and enhance patient satisfaction.

Complications

Non-ablative laser surgery is not without risks, but side effects are much milder than with ablative laser treatment. Depending on the treatment, patients may have erythema and edema, which resolves in hours to days. Rarely are treatments associated with blistering, transient hyperpigmentation, or scarring. In some cases, post-treatment hyperpigmentation has been caused by excessive use of cryogen spray but has resolved with topical bleaching agents.

Patient Instructions

Because the epidermis remains intact after non-ablative laser procedures, minimal postoperative care is required. Ice can be applied to decrease erythema and swelling, and occasionally systemic glucocorticoids may be required.

TREATMENT OF VASCULAR LESIONS

A wide range of vascular lesions are amenable to safe and effective treatment by a class of lasers that take advantage of the principle of selective photothermolysis (see also Chap. 240).

Patient Selection

Vascular lesions can be a significant cosmetic concern for some patients and are generally amenable to laser treatment. Telangiectasias are small, superficial cutaneous blood vessels often appearing on the nose, cheeks, and chin in fair-skinned individuals as a result of actinic damage or rosacea. Other causes of telangiectasias include collagen vascular disease, genetic disorders, hormonal disorders, primary cutaneous disease, and radiation dermatitis. Telangiectasias are often associated with facial erythema, which can manifest as a flushing or blushing disorder. Various laser treatments can target this background discoloration in addition to treating the discrete vascular lesions.

Other types of vascular lesions, including cherry and spider hemangiomas, venous lakes, and angiokeratomas, may respond to vascular laser treatment (Fig. 253-4). Poikiloderma of Civatte, which manifests as a combination of telangiectasia, irregular pigmentation, and atrophic changes in fair-skinned individuals with actinic damage, can also be treated with vascular lasers. Extreme caution must be used when treating this condition, because overly aggressive treatment can worsen the atrophy and hypopigmentation.

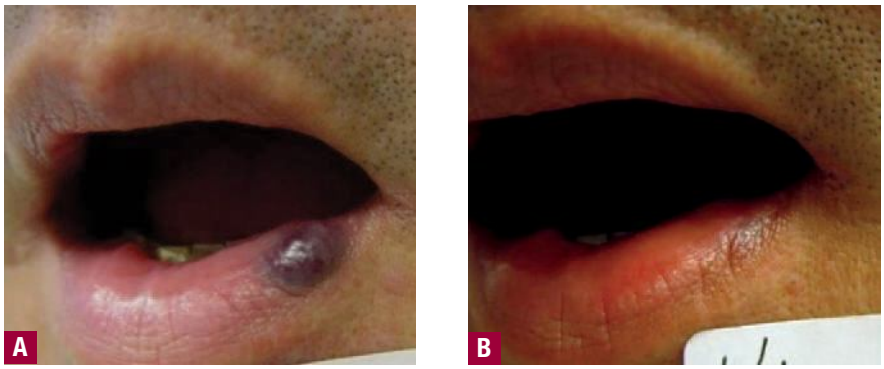
In addition to improving vascular lesions, vascular laser treatments can improve the appearance of hypertrophic scars and keloids. Vascular lasers not only reduce the erythema by eliminating the underlying dilated microvasculature in a scar, they can also reduce the height of the scar and improve the skin surface texture. Multiple treatment sessions are required, and the treatment can be augmented by intralesional injections of corticosteroid with 5-fluourouracil. Newly formed atrophic scars, such as striae rubra, can sometimes be greatly improved with vascular laser treatment, whereas older lesions are less responsive.

Risks and Precautions

Laser treatment of vascular lesions is relatively safe but not without risks (Table 253-3). Higher-energy treatments or treatments with overlapping passes can result in atrophic or hypertrophic scarring. Alterations in pigmentation may result due to the concomitant absorption of 532-nm light by epidermal melanin. Patients with tans or darker skin types must be treated with caution to avoid pigmentary changes.

Patient Positioning

Most cosmetic vascular laser treatments are performed in the office. The patient's



▲ **FIGURE 253-4** Venous lake treated with a potassium-titanyl-phosphate laser. **A.** Before treatment. **B.** After treatment.

eyes are protected with laser surgery goggles or with intraocular metal eye shields if treatment around the eye is required. All clinical personnel must wear laser surgery glasses that specifically absorb the wavelength of light used in the treatment. Flammable gases and other materials must not be present, because vascular lasers are capable of igniting fires.

Equipment

Vascular lesions were one of the first targets of treatment with early lasers. These early lasers, such as the argon laser (488 nm, 514 nm), argon pumped tunable laser (488 to 638 nm), copper and bromide lasers (578 nm), potassium-titanyl-phosphate (KTP) laser (532 nm), and krypton laser (568 nm), emitted continuous energy that was absorbed by oxyhemoglobin in cutaneous blood vessels (see also Table 240-1 in Chap. 240). Their use was limited because the continuous thermal energy often resulted in scarring and pigmentary alterations. The development of pulsed lasers in the 1980s allowed for more precise targeting of the oxyhemoglobin-containing vessels with less thermal and mechanical injury of surrounding tissues (Table 253-4). It is believed that pulsed energy delivered with short pulse widths causes intravascular cavitation, vessel wall fragmentation, and hemorrhage, whereas pulsed energy delivered over longer intervals causes intravascular coagulation and collagen contraction within the vessel wall and surrounding tissue. To reduce epidermal damage, all vascular lasers use an epidermal cooling system, with a cryogen spray or contact cooling.

The flashlamp-pumped PDL uses a high-power flashlamp to excite an organic dye (rhodamine) and produces a pulse of yellow light that is absorbed by oxyhemoglobin. The newer PDLs can deliver a variety of fluences over variable pulse durations (up to 40 milliseconds) to effectively treat many cosmetic conditions (see also Chap. 240). These PDLs can deliver high-energy, shorter pulses of light to treat striae distensae rubra and keloids. Purpura often results at these settings. However, the device is most useful in treating facial erythema and facial telangiectasias at longer pulse durations that do not lead to purpura, which is a barrier to treatment for some patients.

The long-pulse, frequency-doubled Nd:YAG-KTP lasers emit a green 532-nm light that can also improve telangiectasias with minimal purpura. The current KTP lasers deliver energy with pulse durations of 1 to 100 milliseconds through a fiberoptic handpiece with contact cooling. Although the 532-nm light is strongly absorbed by hemoglobin, the laser has a limited depth of penetration, which makes it useful for treatment of superficial facial vessels. Because melanin also absorbs 532-nm light, this laser should be used with caution in patients with darker skin phototypes.

TABLE 253-3
Treatment of Vascular Lesions: Associated Risks

- Post-inflammatory hyperpigmentation
- Post-inflammatory hypopigmentation
- Atrophic scarring
- Hypertrophic scarring

TABLE 253-4
Treatment of Vascular Lesions: Equipment

- Pulsed potassium-titanyl-phosphate lasers
- Pulsed dye, long-pulsed dye, variable-pulsed dye lasers
- Long-pulsed infra-red lasers: Alexandrite, diode, neodymium:yttrium-aluminum-garnet (Nd:YAG)
- Multiplex lasers: Sequential pulsed dye + Nd:YAG
- Intense pulsed light devices

Long-pulsed infra-red lasers such as the alexandrite (755 nm), diode (800 nm), and Nd:YAG (1064 nm) lasers allow deeper penetration into the skin, but their light is absorbed less specifically by hemoglobin than is the light of other vascular lasers (see also Chap. 240). There is still enough absorption, however, to treat superficial and deep reticular veins (up to 3 mm in diameter) in patients with a variety of skin types. More recently, multiplex lasers have been developed that sequentially deliver a PDL (595-nm) pulse followed by an Nd:YAG (1064-nm) pulse at precise intervals. It is theorized that the first PDL pulse induces blood clot formation and methemoglobin conversion, which allows for greater absorption of the Nd:YAG energy. Studies are ongoing to delineate the cosmetic and medical indications for multiplex laser treatment.

IPL devices with cutoff filters that deliver increments of light ranging from 515 to 590 nm have been shown to be effective in the treatment of cosmetic vascular conditions. IPL devices produce a variety of fluences (up to 80 J/cm^2) over 2 to 10 ns in single-, double-, or triple-pulse modes. The light is delivered by a fiber through an 8 × 15 mm or 8 × 35 mm glass window that is pressed directly against the skin. A coupling gel is applied to the skin before light application to protect the epidermis from overheating and improve light penetration. Compared with PDLs, IPL devices require a longer treatment session and potentially a greater number of treatments to achieve similar results.

Anesthesia

Vascular lasers and light sources used for cosmetic indications produce a brief stinging or burning sensation. Treatments are generally tolerated without anesthesia. Because discomfort can build with cumulative laser pulses, treatment of lesions with large surface areas may require topical anesthesia with a eutectic mixture of prilocaine and lidocaine or topical lidocaine. Topical anesthetics are removed a few minutes before treatment to reduce vasoconstriction and interference with laser light delivery. Rarely, local anesthesia with lidocaine or nerve blocks are required for full-face treatment.

Technique

The technique for treatment of vascular lesions will depend on the type and size of vessel to be treated and the patient's

skin type. PDL treatments are delivered through a hand-held fiber optic device with a spot size ranging from 2 to 12 mm. The pulses are placed adjacent to each other with approximately 18 percent overlap to avoid missing areas between pulses. In general, lower fluences are used to treat macular lesions, whereas higher fluences are used to treat more hypertrophic lesions. At short pulse durations, a light gray discoloration of the treated area is the therapeutic endpoint, whereas at long pulse durations transient purpura lasting 1 to 2 seconds is the desired endpoint. Pulsed KTP laser treatment is delivered using a handpiece held perpendicular to the skin surface, and the vessels are traced individually at a speed that heats them without causing epidermal damage. Effective treatment will cause vessels to disappear with a subtle blanching effect.

IPL is delivered with a shorter-wavelength filter (515 nm) in single-pulse mode to treat fine superficial vessels in patients with skin phototype I. Longer cutoff filters (570 to 590 nm) and double- or triple-pulse modes are needed to treat large and deeper vessels. A layer of cool water gel 1 to 2 mm thick is applied to the skin, and then test spots are treated at increasing fluences until a faint erythema without epidermal damage is achieved. The individual pulses are applied adjacent to each other with minimal overlap. A second pass may be made perpendicular to the first pass to prevent reticulation.

Outcomes Assessment

The efficacy of laser and light treatment of vascular lesions depends on the caliber and depth of treated vessels. Small superficial vessels are more responsive than larger, deeper vessels. Lesions with a high blood flow, such as some spider angiomas, are also more difficult to treat. Patient response is assessed at 4 to 6 weeks after treatment, and treatments are repeated if necessary.

Complications

Immediately after treatment, patients may experience erythema and edema, which may last for the next 1 to 2 days. Patients who are treated with a PDL at short pulse durations will develop purpura, which gradually resolves in 1 to 2 weeks. Crusting, blistering, and scarring may result from overtreatment. Given the overlapping absorption spectrum of epidermal melanin, vascular laser treatment can cause hyperpigmentation or hypopigmentation, but this is rarely observed. Suntanned patients and patients with darker skin phototypes should not be treated with KTP, PDL, or IPL devices.

Patient Instructions

Application of cold dressings or ice can help minimize the erythema and edema that develop in the first 24 hours after vascular laser treatment. Crusted or blistered areas should be treated twice a day with petrolatum until they have resolved. Patients requiring multiple treatments should wear sunscreen daily to prevent the risk of laser energy absorption by epidermal melanin in subsequent treatments.

TREATMENT OF COSMETIC PIGMENTED LESIONS

Patient Selection

The treatment of pigmented lesions depends on the type of pigmented lesion being targeted, its anatomic location in the tissue, and whether the pigment is intracellular or extracellular within this tissue. The background skin color must also be considered so that treatment can be directed toward the abnormal pigment while leaving the normal pigmentation intact.

The success of cosmetic treatment of pigmented lesions also depends on certain patient factors. A complete medical history should be taken with specific emphasis on poor wound healing, post-inflammatory hyperpigmentation, bleeding disorders, gold therapy, and isotretinoin use in the previous year. Should any of these factors be present, the surgeon should proceed with extreme caution. In addition, all pigmented lesions should be properly evaluated, and biopsy should be performed on any questionable lesions. Laser treatment does not yield tissue for histopathologic analysis. Before treatment, patients should be counseled that the lesion may require multiple treatments and that the lesion may not clear completely.

Risks and Precautions

Pigmentary and textural changes are the most common complications observed when treating pigmented lesions (Table 253-5). Pigmentary changes occur more commonly in patients who are tanned or have darker skin phototypes. Transient hypopigmentation and, rarely, long-term depigmentation may develop. Hyperpigmentation has been reported in up to 16 percent of cases and is more commonly seen in patients with darker skin phototypes.[6] To avoid pigmentary alterations, patients with tanned skin should not be treated, because this increases their risk of adverse effects. The risk of scarring is small, but the use of Q-switched Nd:YAG lasers at 1064 nm may cause textural change, although this occurs in fewer than 5 percent of cases.

TABLE 253-5
Treatment of Cosmetic Pigmented Lesions: Associated Risks

- Post-inflammatory hyperpigmentation
- Post-inflammatory hypopigmentation
- Allergic reaction to tattoo pigment
- Localized chrysiasis

Patients and practitioners must also be aware that laser treatments can alter tattoo pigments, causing a local or systemic reaction. Local allergic reactions to cadmium sulfide and chromium have been reported, and patients with known allergies to these substances should generally not undergo laser treatment for tattoo removal. Q-switched lasers may also alter cosmetic tattoos containing ferric oxide pigment, creating an immediate paradoxical darkening. It is advised that these eyeliner and lip tattoos first be treated in test spots with single pulses and then observed 2 weeks later to assess clinical outcomes. Often ablative lasers are more effective at removing these lesions without the risk of paradoxical darkening.[7]

Patients should also be questioned regarding medications, because Q-switched lasers have been reported to cause localized chrysiasis in patients who have received parental gold therapy.[8] It is believed that the laser causes a physiochemical transformation of the gold pigments, similar to its darkening effect on cosmetic tattoos.

Patient Positioning

Most laser treatments of cosmetic pigmented lesions are performed in the office, with the patient and all clinical personnel wearing appropriate eye protection. The treatment site is thoroughly cleansed to remove all makeup, sunscreen, and topical anesthetic, which can hinder delivery of the laser energy. If alcohol has been used to clean the area, it must be thoroughly removed before laser treatment, because it could be a

TABLE 253-6
Treatment of Cosmetic Pigmented Lesions: Equipment

source of flash fire development. Because treatment with Q-switched 1064-nm Nd:YAG lasers can cause some tissue and blood splatter, universal precautions should be followed at all times.

Equipment

Lasers used for the treatment of pigmented lesions (Table 253-6) can be categorized as highly selective Q-switched lasers, less pigment-selective lasers, and non–pigment-selective lasers. The Q-switched lasers, including the Q-switched ruby laser (694 nm), the Q-switched alexandrite laser (755 nm), and the Q-switched Nd:YAG laser (1064 nm), are capable of targeting superficial epidermal and deeper dermal pigment. Epidermal pigment–based lesions can also be treated with the Q-switched frequency-doubled Nd:YAG laser (532 nm) and the flashlamp-pumped PDL (510 nm). Long-pulsed pigment-specific lasers, such as the long-pulsed ruby laser, long-pulsed alexandrite laser, long-pulsed diode laser, and long-pulsed Nd:YAG laser, have pulse durations in the millisecond range. These lasers have been shown to treat certain nevi by targeting nests of cells rather than individual melanosmes.[9]

Non-specific ablative lasers such as the CO_2 laser (10,600 nm) and erbium:YAG laser (2940 nm) can remove pigmented superficial lesions secondary to their ablative actions. IPL devices can be used to treat mild pigmentary changes due to photodamage.

Anesthesia

Treatment of the majority of pigmented lesions does not require topical or infiltrative anesthesia. However, treatment of larger tattoos and lesions with large amounts of dermal pigment may require local anesthesia or nerve blocks.

Technique

Superficial epidermal pigmented lesions such as ephelides, solar and labial lentigines, café-au-lait macules, and flat pigmented seborrheic keratoses can be effectively treated with Q-switched ruby (694-nm) lasers, Q-switched alexandrite (755-nm) lasers, 532-nm lasers, short-pulsed dye (510-nm) lasers, and IPL devices (Fig. 253-5; see also Chap. 240). Most lesions respond to one or two treatments spaced 4 to 6 weeks apart. The response of café-au-lait macules is variable, with up to a 50 percent recurrence rate. In general, the laser handpiece is held perpendicular to the skin, and parameters are selected based on the melanin content of the lesion and background skin type. Lower fluences are used for targets containing an abundance of melanin. The desired endpoint is a uniform but faint whitening of the skin without epidermal disruption.

▲ **FIGURE 253-5** Solar lentigines treated with a Q-switched ruby laser. **A.** Before treatment. **B.** After treatment.

Dermal pigmented lesions such as nevus of Ota and pigmentation due to medication can also be improved with the Q-switched pigment-targeted lasers described previously in Equipment. Dermal tattoos are generally treated with lasers that are selective for the various colors of inks (see also Chap. 240). Q-switched ruby and alexandrite lasers are best for treating blue, black, and green ink, whereas short-wavelength lasers such as the short-pulsed dye (510-nm) and Q-switched 532-nm ND:YAG lasers are best for treating red pigments. Yellow-pigmented tattoos are usually resistant to laser treatment. Dermal lesions and tattoos are treated similarly to epidermal lesions, with the desired endpoint being a whitening of the skin with intact epidermis. Treatments are spaced 6 to 8 weeks apart, because clearing of dermal pigment depends on the slow mechanism of phagocytosis (Fig. 253-6).

Outcomes Assessment

Patients should be evaluated 4 to 6 weeks after small test spots within the larger lesion are treated. They should be informed that often multiple treatments are needed to achieve the desired clinical outcome.

Complications

Immediately after laser surgery, the treated area develops a whitening response that typically fades in 20 to 30 minutes. Some patients may develop an urticarial reaction, which can subside within an hour and responds to antihistamines. A crust will form in the treated area; it resolves in 7 to 10 days on the face but may take longer to resolve on non-facial areas. In rare cases blisters, vesicles, scarring, and pigmentary changes may occur.

Patient Instructions

After laser treatment of pigmented lesions, patients may use ice packs, cool compresses, and hydro-occlusive dressings to reduce any postoperative pain. Daily

cleansing of the treated areas with soap and water followed by application of occlusive ointments is recommended until the crusts have resolved. All patients are advised to avoid excessive sun exposure and apply broad-spectrum sunscreen daily.

CHAPTER 254

Liposuction

Aimee L. Leonard
C. William Hanke

PATIENT SELECTION

Liposuction should be regarded not as a method of weight reduction or an alternative to diet and exercise, but as a body-contouring procedure. The ideal candidate is a healthy patient near his or her ideal body weight who has disproportionate, localized adipose deposits resistant to diet and exercise. Liposuction should be avoided in patients with unrealistic treatment goals and those with emotional or psychological instability (i.e., presence of an eating disorder or body dysmorphic disorder). A comprehensive preoperative consultation including a screening questionnaire is used to identify patients who are appropriate candidates. During the consultation, the risks, goals, anticipated results, and expected postoperative course are discussed.

PREOPERATIVE EVALUATION

Taking a thorough medical history will screen for patients who may be poor surgical candidates for liposuction (see Risks and Precautions). Patients at risk for complications should receive medical clearance before surgery.[2,3] A careful review of all medications is essential. All anticoagulant medications, including vitamins and herbal supplements, should be discontinued 2 weeks before surgery. Use of medically necessary anticoagulant therapy is a contraindication for tumescent liposuction. Medications that are metabolized by the hepatic cytochrome P_{450} 3A4 enzyme system should be identified. These medications may interfere with the hepatic metabolism of lidocaine, which leads to the potential for toxicity. They should be discontinued or tapered off 2 weeks before surgery if permitted by the prescribing physician. For patients who are unable to interrupt therapy, a lower maximum dose of lidocaine may be used (i.e., less than 35 mg/kg).

Preoperative laboratory testing includes complete blood count with differential and platelet count, prothrombin time, partial thromboplastin time, and chemistry panel (including liver function tests); serologic testing for human immunodeficiency virus and hepatitis B and C viruses; and serum pregnancy test (for females).[2] An electrocardiogram may be considered when the patient is over the age of 60 or when indicated based on the patient's history or a review of systems.

RISKS AND PRECAUTIONS

Risks and precautions concerning liposuction are presented in Box 254-1.

PATIENT POSITIONING

Proper patient positioning is essential for safe and effective removal of adipose tissue. Specific positioning maneuvers differ by anatomic target site and are used to avoid important anatomic structures and optimize cannula access to fatty deposits.

EQUIPMENT

Liposuction requires the following equipment (Figs. 254-1 and 254-2):

- Tumescent anesthetic solution
- Infiltration needles or cannulas
- Intravenous or peristaltic pump tubing
- Infiltration pump
- Liposuction cannulas
- Aspiration tubing
- Aspiration pump with aspirate receptacles
- Monitoring device and emergency equipment

ANESTHESIA

Lidocaine is the preferred anesthetic for tumescent liposuction.[2] The maximum dose reported to be safe is 55 mg/kg.[4] Normal saline (0.9 percent sodium chloride) is typically used as a vehicle. Sodium

LIPOSUCTION AT A GLANCE

- Liposuction is one of the most commonly performed cosmetic procedures and is widely practiced by dermatologic surgeons.
- The tumescent technique of local anesthesia is one of the most important innovations in liposuction surgery.[1]
- Liposuction performed with tumescent local anesthesia allows for the removal of large volumes of fat.
- Liposuction is characterized by unparalleled safety, rapid patient recovery, and low postoperative morbidity.
- Importantly, liposuction has been demonstrated to be very safe to perform in the office setting, the preferred venue for the procedure when carried out by dermatologic surgeons.

Box 254-1

Risks and Precautions for Liposuction

CONTRAINDICATIONS TO LIPOSUCTION

- Severe cardiovascular disease
- Severe coagulation disorders, including hemophilia
- Pregnancy

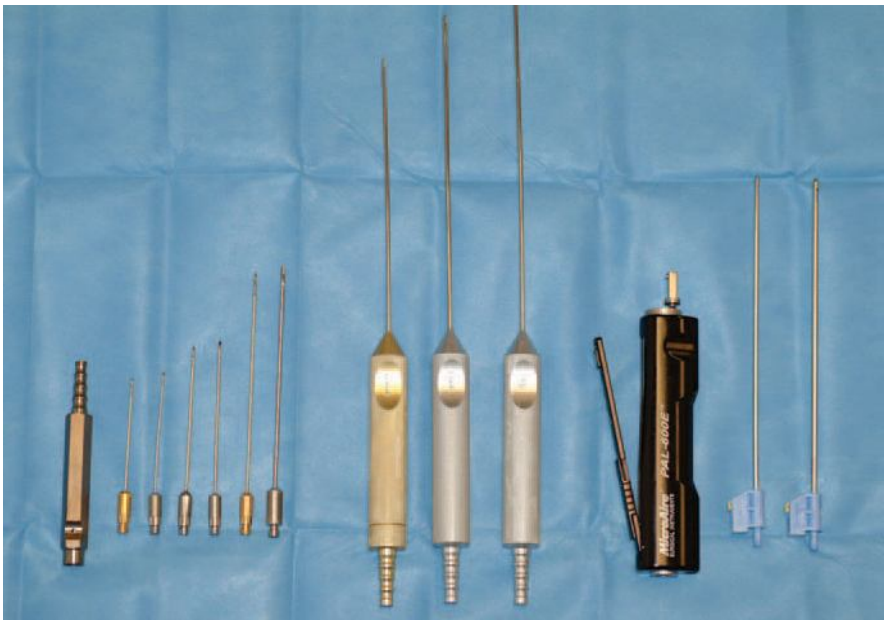
CONDITIONS THAT PUT PATIENTS AT RISK FOR COMPLICATIONS

- History of bleeding diathesis, thrombophlebitis, or emboli (fat or thrombotic)
- History of infectious disease (including hepatitis and human immunodeficiency virus infection)
- Poor wound healing
- Diabetes mellitus
- Immunosuppression
- Prior extensive abdominal surgery
- Hepatic disease
- Renal disease
- Morbid obesity
- Underlying systemic disease with functional limitations
- Use of anticoagulant medications, vitamins, or herbal supplements
- Use of medications metabolized by cytochrome P_{450} 3A4 enzyme system

bicarbonate is used to buffer the solution, and epinephrine is added to augment hemostasis and slow the absorption of lidocaine. The compositions of tumescent lidocaine solutions ranging from 0.05 percent to 0.1 percent are shown in Table 254-1. Higher concentrations of lidocaine provide better analgesia and are useful in treating small or sensitive areas. Lower concentrations provide adequate anesthesia and are used when treating large or multiple areas. Accurate record keeping of tumescent anesthetic solution preparation and administration is critical to avoid lidocaine toxicity.

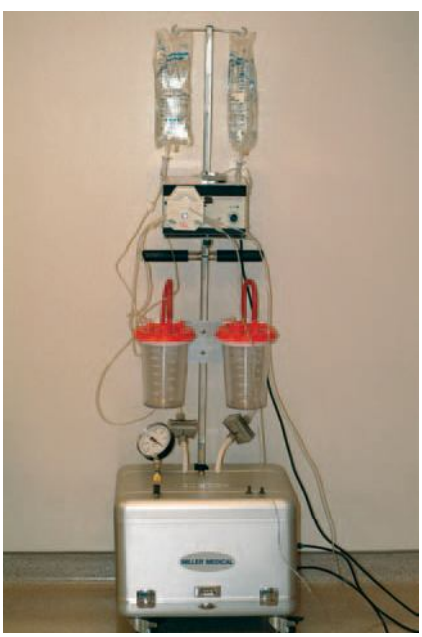
TECHNIQUE

With the patient standing, the target areas for treatment as well as entry sites for cannula insertion are outlined with a permanent marker. The patient is brought to the procedure table and undergoes sterile preparation. Entry sites are anesthetized locally using 1 percent lidocaine with 1:100,000 epinephrine. These sites are then incised with a No. 11 blade. An infiltration cannula is inserted, and tumescent anesthesia fluid is delivered to the subcutaneous space. Rates of infiltration and amounts of fluid delivered vary depending on target area and patient tolerance.



▲ **FIGURE 254-1** A selection of liposuction cannulas, including hand cannulas (*left*) and powered cannulas (*right*). (Used with permission from C. William Hanke, MD.)

Liposuction aspiration cannulas vary in diameter, tip style, and tip configuration. One innovation is powered liposuction using a motorized cannula. In general, larger cannulas with tapered tips and multiple distal apertures allow easier fat removal but also increase tissue injury. The choice of cannula depends on anatomic site as well as surgeon preference and experience. The cannula is inserted into entry sites with the tip apertures facing downward, away from the dermis. Tunneling with the cannula is performed in linear, even strokes with the surgeon's dominant hand, with the non-dominant hand, or "smart hand," controlling cannula tip position at all times. The majority of suctioning should be aimed parallel to the axis of lymphatic drainage to minimize tissue trauma. Uneven or overly aggressive suctioning can lead to contour irregularities and should be avoided. Endpoints can be measured as the time spent in a given area, the amount of fat suctioned, and assessment of the target area by palpation. The transition from yellow adipocyte-rich aspirate into fat-sparse serosanguineous tumescent fluid is an additional endpoint. Suctioned aspirate volumes and vital signs are recorded throughout the procedure.



▲ **FIGURE 254-2** Liposuction equipment including (from top to bottom) tumescent anesthetic solution, infiltration pump and tubing, aspirate receptacles, and aspiration pump. (Used with permission from C. William Hanke, MD.)

OUTCOMES ASSESSMENT

Several studies support the excellent safety profile and high rates of patient satisfaction observed with tumescent liposuction. A 1995 survey of dermatologic surgeons who performed tumescent liposuction on 15,336 patients found no fatalities or serious complications. There were no adverse events that necessitated hospitalization.[5] In 2002, Housman et al. reported a serious adverse event rate of 0.68 per 1000 cases in a survey of 267 dermatologic surgeons who performed 66,570 liposuction procedures. No deaths were reported.[6] In a prospective study involving 688 liposuction patients, Hanke et al. found a major

TABLE 254-1
Tumescent Liposuction Solutions

	0.1%	0.075%	0.05%
Sodium chloride 0.9%	1000 mL	1000 mL	1000 mL
Lidocaine 1%	100 mL	75 mL	50 mL
Epinephrine 1:1000	1 mL	1 mL	1 mL
Sodium bicarbonate 8.4%	10 mL	10 mL	10 mL

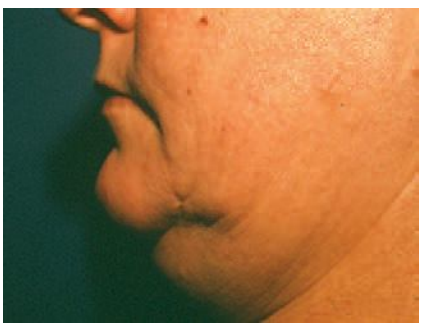
complication rate of only 0.14 percent and a minor complication rate of 0.57 percent. Eighty-four percent of patients reported high levels of satisfaction with the procedure[7] (Figs. 254-3 and 254-4).

COMPLICATIONS

The majority of medical and surgical complications from tumescent liposuction, such as bleeding, hematoma, infection, and lidocaine toxicity, can be avoided by comprehensive perioperative patient evaluation and adherence to published guidelines of care. Aesthetic complications such as surface irregularities, persistent edema, and suboptimal target area fat reduction can be minimized by proper patient selection, patient education, and good technique. Dermatologic surgeons performing liposuction should be knowledgeable about the prevention and management of all potential intraoperative and postoperative complications.

PATIENT INSTRUCTIONS

Anticipated sequelae of tumescent liposuction include copious drainage from cannula entry sites, ecchymoses, edema, soreness, postural dizziness, and temporary dysesthesia. Proper education and instructions regarding diet, activity, and use of compression garments prepare patients for the postoperative period. The patient must be discharged to the care of a family member or friend. Patients are encouraged to ambulate and avoid immobilization. Heavy exercise and hot baths and showers should be avoided.



▲ **FIGURE 254-3** Liposuction of the neck, preoperative. (Used with permission from C. William Hanke, MD.)

▲ **FIGURE 254-4** Liposuction of the neck, postoperative. (Used with permission from C. William Hanke, MD.)

MONITORING AND FOLLOW-UP

A series of follow-up visits is scheduled to assist the patient through the immediately postoperative period and to assess the long-term surgical outcome. Postoperative healing from liposuction is characterized by a protracted period of edema resolution followed by subsequent skin contracture, which leads to a delayed final treatment result. Taking preoperative and postoperative photographs and weight measurements is essential to address patients' concerns and assess treatment response. Patients are encouraged to wait at least 6 months before judging the final cosmetic result. The performance of touch-up procedures in a treated area should be deferred for at least 1 year.

CHAPTER 255

Soft-Tissue Augmentation

Lisa M. Donofrio

GENERAL INJECTION TECHNIQUES

With the possible exception of autologous fat, all soft-tissue fillers are injected through a sharp needle. The level of injection into the skin depends on the type of filler injected, the properties of the filler, the area injected, and the desired result. Threading is a technique in which the needle is inserted into the skin and the filler is deposited in a linear fashion along the track of the needle as it is being withdrawn. Fanning is a type of threading in which, instead of inserting the needle into a new area each time, the needle is just withdrawn so that a new track can be made radially adjacent to the last. In the "push-ahead" technique, an injection is made in an antegrade direction, so that the injectable material flows from the tip of the needle and hydrodissects the tissues as it flows. This technique is often used in areas in which bruising is more likely to occur along the needle track, such as the upper lid and brow. In the depot method of injection, small "pearls" of material are deposited serially, usually along a fold or deep by bone. Cross-hatching is an approach used to diffusely cover an area with the injected material. In this method, linear threads are lined up in

SOFT-TISSUE AUGMENTATION AT A GLANCE

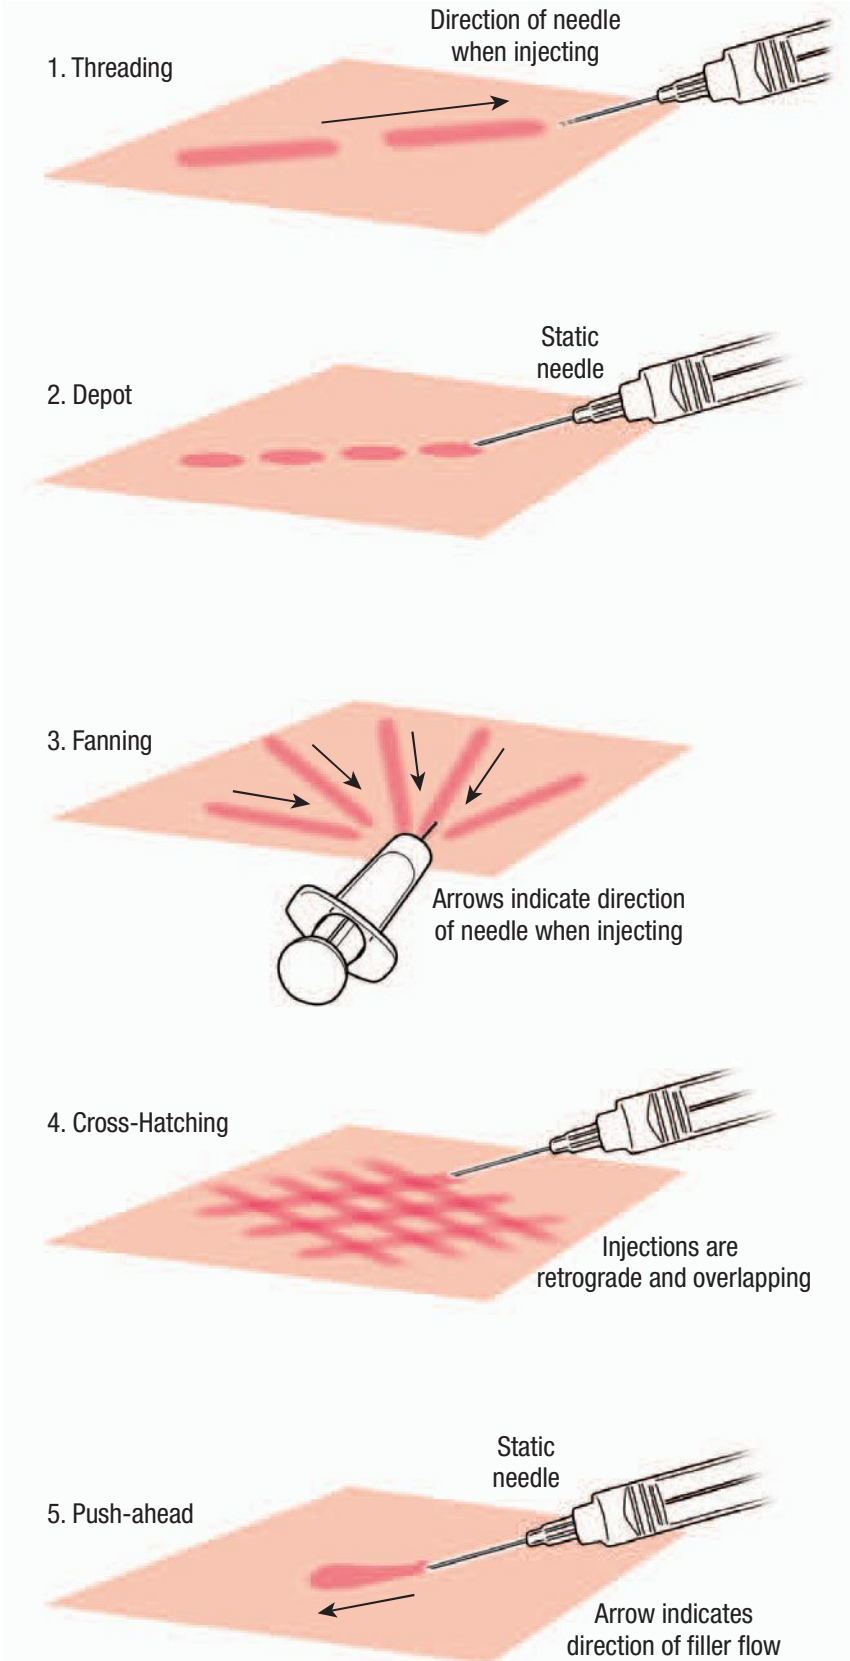
- Soft-tissue augmentation is an excellent way to restore the contours of youthful fullness to an aging face.
- It is one of the most common cosmetic procedures performed in dermatology practices.
- Soft-tissue fillers vary in their longevity, allergenic potential, safety, and applications. There is no perfect filler at this time, but the ideal soft-tissue filler should be nonallergenic, noncarcinogenic, nonteratogenic, biocompatible, nonmigratory, and affordable, and should provide effects that are reproducible and long lasting yet reversible.
- Literally hundreds of soft-tissue fillers are available worldwide.
- This chapter focuses on those fillers that are approved by the U.S. Food and Drug Administration for soft-tissue augmentation or are commonly used off label for filling rhytides or skin lines or giving the face a more global change of appearance. Fillers for treatment of lipodystrophy, including lipodystrophy induced by highly active antiretroviral therapy, are discussed in Chap. 69.

succession and a second series of rows is then layered at right angles on top of the first. Fig. 255-1 illustrates the different injection techniques. Whatever the technique chosen, care should be taken in highly vascular areas to avoid intravascular injection of filling material. The plunger of the syringe should be pulled back to check for blood flow, and if it is found, the needle should be withdrawn and repositioned.

COLLAGENS

Patient Selection

Collagen fillers are indicated for volume enhancement of the nasolabial folds, labiomental crease, and lips as well as the attenuation of fine lines around the mouth and eyes. They are not a single filler but a group of fillers with different injection properties, flow characteristics, and viscosities. Very little bruising or swelling occurs with collagen injections, so collagen injections are appropriate for patients who cannot afford any "downtime." As with all fillers, results often depend on the amount injected and the goals of the patient. All collagen products should be avoided in patients with a history of collagen vascular disease, a positive skin test result, or known allergy to collagen products. Table 255-1 contains relevant informa-



▲ **FIGURE 255-1** Injection techniques.

TABLE 255-1
Features of Soft-Tissue Fillers

Filler	Uses	Type	Placement	Complications	Longevity
Zyderm I	Treatment of fine lines	Bovine collagen	Papillary dermis	Allergic reaction, misplacement	2–4 mo
Zyderm II	Treatment of medium lines, acne scars	Bovine collagen	Mid-dermis	Allergic reaction, misplacement, lumps	3–5 mo
Zyplast	Treatment of medium to deep folds, lips, acne scars	Bovine collagen	Deep dermis	Allergic reaction, misplacement, lumps	3–6 mo
CosmoDerm	Treatment of fine lines	Human-derived collagen	Papillary dermis	Allergic reaction, misplacement	2–4 mo
CosmoPlast	Treatment of medium to deep folds, lips, acne scars	Human-derived collagen	Deep dermis	Allergic reaction, misplacement, lumps	3–8 mo
Restylane	Treatment of medium to deep folds, lips, acne scars, periorbital hollows	Non–animal-derived stabilized hyaluronic acid	Mid to deep dermis	Allergic reaction or inflammation, blue discoloration, misplacement, lumps	5–8 mo
Perlane	Treatment of deep folds, lips, scars; facial contouring	Non–animal-derived stabilized hyaluronic acid	Deep dermis or superficial subcutis	Allergic reaction or inflammation, blue discoloration, misplacement, lumps	6–12 mo
Juviderm	Treatment of medium to deep folds, lips, acne scars	Non–animal-derived stabilized hyaluronic acid	Mid to deep dermis	Allergic reaction or inflammation, blue discoloration, misplacement, migration, lumps	5–8 mo
Radiesse	Treatment of deep folds, nipple reconstruction, nasal reconstruction, jawline augmentation	Calcium hydroxylapatite	Deep dermis to superficial subcutis	Nodules (especially in lips and periorbitally), misplacement with demarcation of product	6–? mo
Sculptra	Treatment of HIV lipoatrophy, cheek and temple hollows	Poly-L-lactic acid	Deep dermis to superficial subcutis	Visible and palpable papules	2 yr or longer
Autologous fat	Pan-facial filling, especially periorbital area	Autologous fat	Subcutaneous tissue	Bumps, vascular occlusive events with injudicious placement	5 yr or longer
Silikon 1000	Treatment of scars, HIV lipoatrophy, lips, deep folds	Silicone oil	Deep dermis	Delayed granuloma formation, migration	Permanent

HIV = human immunodeficiency virus.

tion regarding various types of collagen and other soft-tissue fillers.

Formulations

Bovine collagen (Zyderm I and II, Zyplast*) has been approved for use in the United States since 1981 and, until recently, was the only filler approved by the U.S. Food and Drug Administration (FDA) for soft-tissue augmentation. Bovine collagen products are derived from the hides of a closed herd of American cattle. Before the use of any form of bovine collagen, two skin tests must be performed 4 weeks apart to ensure that allergic reactions to the bovine proteins are avoided. A single skin test alone will fail to identify approximately 25 percent of allergic patients. Human-derived collagens (CosmoDerm, CosmoPlast) are newer to the market. They are produced from a single human fibroblast cell line. Batches are tested for purity and sterility. Due to their homologous nature, synthetic human collagen does not require pre-testing for allergenicity. Three forms of bovine collagen and two forms of human-derived collagen are available, each appropriate for a different level of injection into the dermis. Bovine collagen must be kept refrigerated until just before use. The least viscous form of bovine collagen (Zyderm I) contains 3.5 percent non–cross-linked collagen by weight and is appropriate for injection into the papillary dermis for the correction of fine lines. The second non–cross-linked form has 6.5 percent bovine collagen by weight and is injected into the upper reticular dermis as a treatment for deeper lines and acne scars. Finally, a third form consists of 6.5 percent bovine collagen cross-linked with glutaraldehyde to provide stability against degradation. This is the most viscous of the three bovine forms and is appropriate for treatment of deep folds and lip augmentation. Human collagen is available in a non–cross-linked and a cross-linked form, both with 35 mg/mL of collagen. As with bovine collagen, the non–cross-linked form is more appropriate for injection into fine lines through a small-bore needle and the cross-linked form is more appropriate for treatment of deeper lines, folds, and acne scars, and for lip augmentation.

Anesthesia

All collagens come in pre-filled syringes that contain, in addition to the collagen product, phosphate-buffered saline and 0.3 percent lidocaine. If additional anesthesia is required, lidocaine 4 percent or tetracaine 20 percent can be applied topically in advance. For patients more sensitive to pain, 1 percent lidocaine may need to be administered locally into the area to be infiltrated. If lip augmentation is being carried out, infraorbital nerve blocks may be established with 2 percent lidocaine via the intra-oral or transcutaneous route.

*It is the editors' policy not to use trade names in this book. However, in certain instances, the editors had to depart from this policy to avoid confusion.

Technique

Collagen products are most easily injected with the patient reclining at a 45° angle and the injector positioned to the side of the table. Injection techniques may include a combination of threading, depot, and fanning. The more viscous forms of collagen (Zyplast, CosmoPlast) are best injected through a 30-gauge needle. For the non–cross-linked forms (Zyderm I and II, and CosmoDerm) a 32-gauge needle may be substituted. Use of this smaller-bore needle is especially helpful for attenuation of fine lines around the mouth and eyes or for any other situation in which more control over small injection volumes is needed. Injection of the non–cross-linked forms occurs in the high dermis and should lead to blanching. Because collagen products lose volume after injection, overcorrection of the area injected by 50 percent to 100 percent is desirable.

Post-Procedure Instructions

In the period immediately after injection, the application of ice is recommended to assist with vasoconstriction and help prevent ecchymosis. Effects of the local anesthesia will last from 20 minutes to 90 minutes depending on the anesthetic used. Patients should be warned that immediate results such as swelling and unevenness are secondary to overcorrection and will subside over the course of hours. Patients may apply makeup immediately after injection and go about their daily activities as usual.

Unique Complications

Complications unique to collagen injection include delayed hypersensitivity or allergic reactions to the bovine or human proteins. Although such reactions are rare, they can be seen even with a negative skin test result in approximately 1 percent of patients. These can manifest as either granulomatous reactions or sterile abscess formation. Treatment involves intralesional injection of dilute corticosteroid, administration of oral antibiotics, and reassurance. These adverse events can take up to a year to resolve on their own.

Longevity

Bovine collagen lasts from 2 to 6 months depending on the type used, the level of injection, the site injected, and the amount used. Human-derived collagen appears to last slightly longer.

HYALURONIC ACIDS

Patient Selection

Hyaluronic acid–derived fillers are a good choice for patients who desire a longer period of correction or more volume enhancement. They are more versatile than the collagen products and can be used for augmentation of the nasolabial fold, labiomental crease, lips, cheeks, and periorbital areas. Patients often feel that the hyaluronic acid fillers are softer and more natural in appearance than the collagens, but they need to be warned about the risk of increased erythema, edema, and bruising associated with these products.

Formulations

Hyaluronic acid is a polysaccharide that is homologous throughout the animal kingdom. Injectable FDA-approved forms include a non–animal-derived stabilized hyaluronic acid product (NASHA) made through a bacterial fermentation process and an avian-derived version isolated from cocks' combs. Brands of injectable hyaluronic acids differ not only in their derivation but also in their concentration of hyaluronic acid per milliliter of product, type of cross-linking or stabilizing agents, viscosity, and particle size. All NASHA products are made en bloc initially and then passed through a sieve to create smaller particles. Restylane contains 20 mg/mL of hyaluronic acid with 100,000 gel particles per milliliter. Perlane is another product in the Restylane family. It also contains 20 mg/mL of hyaluronic acid, but the particles are larger, which provides a product concentration of 10,000 gel particles per milliliter. The smaller particle size of Restylane permits injection through smaller-gauge needles into finer wrinkles. The newest NASHA product, Juviderm, is available in two formulations: Juviderm Ultra, containing 24 mg/mL of hyaluronic acid, and Juviderm UltraPlus, containing 30 mg/mL of hyaluronic acid. Another hyaluronic acid, Hylaform, contains 6 mg/mL of hyaluronic acid highly cross-linked with divinyl sulfide. Hylaform is avian-derived and thought by some to possess elastic properties superior to those of the NASHA products. All hyaluronic acid products are prepackaged in filled syringes that require no refrigeration.

Anesthesia

Unlike collagens, hyaluronic acids do not come combined with lidocaine. Due to their high viscosity they can cause significant discomfort on injection. It is therefore recommended that, at a minimum, a topical anesthetic be applied before injection. This usually results in adequate anesthesia for periorbital, nasolabial fold, and labiomental crease injections; however, if lips or perioral rhytides are being treated, an ancillary local infiltration of 1 percent lidocaine or segmental nerve block is indicated.

Technique

Hyaluronic acids should be injected with the patient in a position that elicits the defect or creases to be treated and offers ease of injection to the operator. This is best accomplished by reclining the patient to a 45° angle. All the hyaluronic acid products come with a needle in the gauge of choice for ease of injection and preservation of the physical properties of the gel. Due to their viscoelastic properties, however, hyaluronic acids can often be injected through smaller-gauge needles. For instance, Restylane is prepackaged with a 30-gauge needle, but changing to a 32-gauge needle allows for more precise injection of vertical lip rhytides. Hyaluronic acids are injected in most areas via threading, depot, or fanning. They are particularly amenable to cross-hatching in areas in which a greater density of augmentation is desired. In particular, when hyaluronic acid is injected into the nasolabial fold it is important to span the width of the fold with a serial threading technique and then cross-hatch at right angles. This gives structural integrity to the fold and prevents the undesirable result of merely moving the fold medially. The same technique can be used in the labiomental crease. Lip injections are made using a depot or threading technique, either along the vermillion border, in the body of the lip, or in a combination of both. Perhaps one of the most exciting applications of hyaluronic acids is the correction of tear trough deformity or suborbital hollows. Injections are made either under the orbicularis oculi muscle near the orbital bone or subdermally above the muscle. A depot method of injection is preferred in which very small amounts of hyaluronic acid are deposited on each pass. The push-ahead technique is preferred for the sub-brow area. After injection the area should be vigorously massaged to disperse the product and minimize aggregation of gel particles. Although periorbital injection of hyaluronic acid

results in high levels of patient satisfaction, it is an advanced injection method best left to those with the greatest experience in this sophisticated technique.

Post-Procedure Instructions

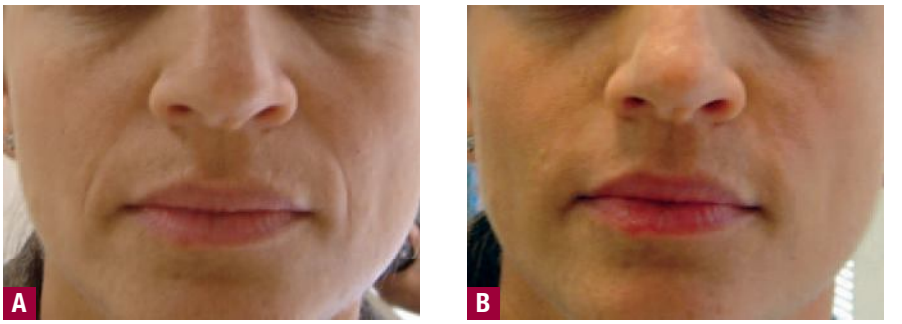
The application of ice immediately after the procedure and periodically throughout the day is recommended after the injection of hyaluronic acid. Patients are instructed to avoid manipulation of the treated area and extremes of temperature for the first 48 hours after injection. If the lips were treated in a patient with a history of cold sores, then an antiherpetic medication should be administered for 5 days beginning the day before or the day of the procedure. Patients are instructed to return to the office if they experience any problems such as redness, purulence, or nodule formation.

Unique Complications

Most complications result from improper application of the product. Placement of this clear gel too superficially results in a blue discoloration. Placement of too large an aliquot can result in a non-inflammatory bump. Most ill-placed hyaluronic acid can be released by incising with a 20-gauge needle and expressing the material. Hyaluronic acid products also contain small amounts of impurities that can cause hypersensitivity reactions. Patients can react to sterile bacterial proteins (Restylane, Perlane) or avian proteins (Hylaform) by forming sterile abscesses or granulomatous inflammatory nodules. It has been shown that these nodules, which appear clinically to be granulomatous, may in fact be small foci of infection. Treatment with an anti-staphylococcal antibiotic is the initial treatment of choice. If no resolution occurs, dilute intralesional corticosteroids can be administered or hyaluronidase can be injected to cause rapid dissolution of the product.[1]

Longevity

In general, the longevity of augmentation is greater for the more highly cross-linked or stabilized forms and increases with increasing viscosity and particle size. Hyaluronic acid–based products are broken down via isovolemic degradation; they maintain a constant volume throughout their degradation because of their ability to bind water. This property makes possible a very long-lasting product.



▲ **FIGURE 255-2** Thirty-five-year-old woman before (**A**) and after (**B**) infiltration of Restylane into the nasolabial folds.

In a double-blind multicenter study, Restylane was found superior to Zyplast at all postinjection time points. At 6 months, 67.2 percent of Zyplast-treated folds had returned to their baseline severity, as opposed to only 29.9 percent of Restylane-treated folds.[2] In a study comparing Perlane to Hylaform, at 6 months after treatment, the proportion of patients showing improvement in the Wrinkle Severity Rating Scale score of the nasolabial folds was higher in the group treated with Perlane (75 percent) than in the group treated with Hylaform (38 percent).[3] Treatment-related adverse events were more frequent with Perlane, but local injection-site reactions were mild or moderate in intensity, transient, and no more frequent after Perlane retreatment. In a head-to-head study comparing the tolerability and efficacy of Restylane versus Hylaform in the treatment of nasolabial folds, Restylane demonstrated higher efficacy and patient satisfaction ratings than Hylaform at 12 weeks.[4] Although forcing Restylane through a 32-gauge needle is common in clinical practice, this has been shown to cause the hyaluronic acid to break up into smaller particles. The effect of this on the longevity of the product is unknown. Fig. 255-2 shows a 35-year-old woman before and after Restylane treatment of the nasolabial folds.

POLY-L-LACTIC ACID

Patient Selection

Poly-L-lactic acid (PLLA; trade name Sculptra) is FDA approved for the treatment of lipoatrophy associated with human immunodeficiency virus (HIV) infection. In Europe it has been used for many years as a cosmetic volume enhancement agent. Currently in the United States, PLLA is gaining popularity as a no-downtime, long-lasting filler with a wide range of applications. PLLA's uniqueness lies in the fact that it is not a direct filling agent but rather a biostimulatory agent, eliciting tissue thickening over the course of many months and many treatment sessions. It is therefore the ideal filler for someone desiring a gradual, subtle change. Because PLLA works by initiating a foreign-body tissue response, it is not suited for patients taking immunosuppressive or anti-inflammatory drugs, and it appears to work most efficiently in younger patients. PLLA can be used for volume enhancement in the nasolabial fold, labiomental crease, chin, jawline, temples, and, with care, periorbital area. Some practitioners have found it to provide good filling for the dorsum of the aging hands. It is not recommended for use in the lips.

Formulation

PLLA is the same substance used in the formulation of absorbable suture material and is biocompatible and biodegradable. It is supplied in a glass bottle as a lyophilized powder containing carboxymethylcellulose as an emulsifier and mannitol as an osmotic agent. Injection of PLLA on repeated occasions presumably initiates an immune response that eventually leads to fibroblast activation and collagen deposition. High-level ultrasonographic images taken before and after a series of treatments in study patients confirms the presence of a zone of dermal thickening, but the exact mechanism is unknown.

Anesthesia

PLLA must be reconstituted at least 2 hours in advance of use. Some practitioners suggest reconstitution at least 8 hours before treatment to fully suspend and hydrate the particles of PLLA. The package insert recommends reconstitution with 3 to 5 mL of sterile water, but

the consensus of physicians currently using the product is to reconstitute with 5 mL of diluent at a minimum. It is therefore possible to reconstitute the product in advance with 4 mL of sterile water and immediately before injection to add 1 mL of 1 percent lidocaine to the bottle. This tempers the pain on injection. In addition, patients may want to apply a topical anesthetic containing either 4 percent lidocaine or 20 percent tetracaine in advance of treatment.

Technique

PLLA is injected through a 26-gauge

0.5 percent apraclonidine or 2.5 percent phenylephrine eyedrops (see Fig. 256-6). These will produce 2 to 3 mm of elevation of the lash margin, and administration may be repeated at intervals until the distant diffusion effect of the botulinum toxin on the levator muscle disappears, usually in 2 to 3 weeks.

Horizontal Forehead Lines

The frontalis is treated at the horizontal equator of the forehead or above to avoid inactivation of the lower third of the frontalis muscle, which is responsible for suspension and movement of the eyebrows (see Figs. 256-4 and 256-7). Twelve to 20 units of botulinum toxin are placed in four or five divided doses equidistantly along the forehead equator. If too large a dose is applied or injection sites are placed too low, brow ptosis and loss of brow arch are produced, which leads to an unpleasant, heavy sensation in the brow as well as an aesthetically unattractive appearance.

Unlike in the treatment of eyelid ptosis, there is no comparable adrenergic agent available to reverse brow ptosis induced by botulinum, and the patient must wait several weeks for the effect to wear off. In a patient who has never received botulinum toxin before, it is wise to separate the glabellar area from the forehead area and to wait a couple of weeks between treating the two to avoid the possibility of overtreatment and brow ptosis. Many patients find even the smallest drop in brow position very bothersome, and great care should be taken to avoid this complication of aesthetic treatment.

Crow's-Feet

The rhytides at the corners of the eye respond favorably to injections of toxin; however, patients frequently confuse true crow's-feet rhytides with the dynamic expression lines that appear across the malar eminence laterally in conjunction with smiling and contraction of the zygomaticus muscles. Toxin may successfully ameliorate true crow's-feet, which radiate directly from the lateral canthus and are associated with contraction of the orbicularis oculi muscles by themselves. But the "smile lines" that appear over the malar eminence often lie in wait for the unwary injector. Placing toxin at or below the malar eminence in an attempt to weaken these lines may lead to paralysis of the zygo-

◀ **FIGURE 256-4** Sites of injections on the forehead. The corrugator and procerus muscles are weakened by carefully positioning five injections of botulinum toxin of 5 units each (*open circles*). Forceful knitting of the brow is prevented. To weaken the frontalis muscle, injections are placed in four or five divided doses along the forehead equator (*closed circles*).

▲ **FIGURE 256-5** Before botulinum toxin treatment of the corrugator and procerus muscles (*upper panel*) and 1 week after treatment (*lower panel*).

▲ **FIGURE 256-6** Patient who developed ptosis of the right upper eyelid due to diffusion of the botulinum toxin from the area above the mid-brow down into the levator muscle of the upper eyelid. The lower photograph shows the patient approximately 1 minute after instillation of two drops of apraclonidine 0.5 percent ophthalmic solution into the right eye. Direct adrenergic stimulation of Müller's muscle occurs, which lifts the lid temporarily. The drops may be administered every 4 hours as needed. The botulinum-induced ptosis resolves spontaneously, usually in 3 weeks or less.

maticus muscles and a drooping corner of the mouth that cannot spontaneously be raised, so that the patient may acquire a post-stroke appearance.

To safely approach crow's-feet, the toxin is usually placed at one to three injection points approximately 1 cm lateral to the lateral canthus. Some practitioners place all the drug at one point, and others distribute the dose evenly among three points. Typical doses range from 10 to 18 units depending on the estimate of muscle mass and activity.

Great care must be taken to make the injections into the skin only, raising wheals or blebs that can be gently massaged down. Intramuscular injection in this area will reliably produce unwanted bruising because of the rich venous plexus underlying the skin in this region. The toxin will readily diffuse from the blebs into the underlying orbicularis muscle, relaxing the grip on the overlying skin and smoothing out the wrinkles. As previously mentioned, care must be taken to avoid injecting too low down onto the malar eminence, where diffusion may affect the zygomaticus major muscle and disrupt the symmetrical movement of the corner of the mouth in smiling.

The patient being treated for crow's-feet should have good lower eyelid tarsal tone to avoid the appearance of senile ectropion from too much laxity of the lower eyelid. Pre-treatment of the crow's-feet area is very useful as an adjunctive technique before laser resurfacing. It prevents the problem of rhytides being readily re-formed by repeated squinting during the postoperative healing period, in which case the resurfacing may give rise to more noticeable lines than existed before the resurfacing.

Combination Therapy

As clinical experience accumulated with these commercial botulinum toxin products, experts in soft-tissue augmentation soon recognized that a synergy exists between soft-tissue fillers and neurotoxins.[15] Concomitant with the rise in the use of botulinum neurotoxin for cosmetic applications, the marketplace for soft-tissue augmentation expanded with the introduction of injectable hyaluronic acid gels (see Chap. 255). These agents provided the first new directions in cosmetic therapy since the introduction of solubilized bovine collagen in the mid-1970s. The ability to control both muscles of expression and their secondary lines and folds, and to repair age-related volume changes in subcutaneous tissue has revolutionized minimally invasive cosmetic techniques.

Many patients have eagerly embraced simultaneous treatment with both fillers and botulinum toxin to achieve a natural look and forego more traditional incisional surgery. As an example, patients frequently combine treatment of the upper third of the face (glabellar frown lines, horizontal forehead lines, and crow's-feet) with volume restoration of the lower and middle face (lip enhancement, filling of nasolabial fold and marionette lines, chin and cheek augmentation) (see Chap. 255).

Hyperhidrosis

Focal axillary hyperhidrosis is successfully treated with botulinum toxin by using Minor's starch-iodine test to map out the extent of surface area in the axillary vault that is affected. Anesthesia may be achieved with a eutectic mixture of local anesthetics but is usually not needed due to the relative insensitivity of the axillary skin (see Chap. 243). Doses of 2.5 to 4.0 units of botulinum toxin are placed every 1 to 2 cm as intradermal injections in axillary skin. Reliable anhidrosis is produced within 72 hours and will last for 8 to 12 months with doses of 50 units per axilla (Fig. 256-8). The duration of effect appears to be dose related, and doses of up to 200 units (Dysport) per axilla have been reported to produce dryness for up to 29 months.[16] Aside from insignificant bruising from the needle trauma, there are no apparent side effects.

Palmar hyperhidrosis (Fig. 256-9) is more challenging to treat because of (1) the more limited diffusion of the toxin in palmar skin, (2) the pain on injection, and (3) the generally predictable incidence of temporary weakness in the hand.[9] Anesthesia is achieved with regional wrist blocks of the median, ulnar, and radial nerves using lidocaine 1 percent to 2 percent without epinephrine. Approximately 100 to 150 units of botulinum toxin are needed to treat a single palm, divided into 50 to 60 intradermal injections of 2 to 3 units each. Onset of anhidrosis peaks in 5 to 7 days and is accompanied by minor weakness of the intrinsic muscles of the hand, which makes tasks requiring strength and stability (e.g., pushing a button through a

▲ **FIGURE 256-7** The upper half of the frontalis muscle is weakened by injecting four or five sites equidistantly along the equator of the forehead with a total of 16 to 20 units of botulinum toxin. Patient is shown before treatment (*upper panel*) and 1 week after treatment (*lower panel*).

▲ **FIGURE 256-8** Minor's starch-iodine test is used to demonstrate the area of axillary sweating (*top panel*). The pattern of intradermal botulinum toxin injections is shown with the starch-iodine material in place to highlight the injection points (*middle panel*). One week later the treated axilla shows a negative result on the starch-iodine test (*bottom panel*).

buttonhole) difficult to perform. The weakness usually subsides within 3 weeks, whereas the anhidrosis persists for several months. There is wider variation in response to palmar treatment than to axillary treatment, with anhidrosis lasting from 4 to 12 months, which probably reflects the technical difficulties in achieving even dispersion of the toxin through the palmar skin.

SIDE EFFECTS AND COMPLICATIONS

Minor needle trauma and bruising on injection with a 30-gauge needle are insignificant short-term complications of botulinum toxin injection, and use of a smaller-gauge needle (31 gauge or 32 gauge) will minimize needle trauma. Minor discomfort can be made more tolerable in some patients by pre-treating the injection site areas with topical anesthetic and using sterile saline with preservative as a diluent, which greatly reduces the sensation of injection.

The more problematic complications to consider are eyelid ptosis, which can occur after injections in the glabellar brow (see Fig. 256-6); brow ptosis from overzealous treatment of the frontalis muscle; transient lid edema from periocular injections; headaches after injections anywhere in the upper third of the face; and palmar weakness after injections for hyperhidrosis.

Antibody-mediated resistance appears to be an exceedingly rare event and of little clinical consequence in cosmetic dermatologic uses of botulinum toxin. Although millions of doses have been given to date, there is no well-documented evidence of the development of immunologic resistance in patients treated with cosmetic doses. Resistance continues to be observed in patients treated for cervical dystonia, albeit at much lower rates than in the early years, probably due to the lower protein content of current formulations.

Eyelid ptosis is thought to be best avoided by carefully placing the mid-brow injections at a minimal distance of 1 cm from the superior orbital rim, keeping the injection rate slow and gentle, and having the patient avoid prone positions and sleeping for 2 hours after injection.

Restricting injections to the upper two-thirds of the frontalis and reducing doses to the minimum necessary to produce the desired clinical effect may minimize brow ptosis. Headaches as a rebound phenomenon after facial injections of botulinum toxin may be triggered by unopposed muscle groups, but their etiology is unclear. Usually nonsteroidal anti-inflammatory agents are sufficient to treat them, unless the patient experiences migraines, in which case the patient's usual migraine medication will be required.

In hyperhidrosis, palmar weakness is a predictable consequence of injecting the palms. It is transient and dealt with

▲ **FIGURE 256-9** Hands showing response to Minor's starch-iodine test. The left hand was not treated. The right hand received 100 units of intradermal botulinum toxin A 1 week before the photograph was taken.

by clear pre-injection counseling. There is no similar effect of any clinical significance in either the axillae or the feet.

SUMMARY

The development of botulinum toxin treatment has brought great creativity and capability to cosmetic dermatologic therapy. Further evolution will occur as new serotypes come to market and as greater therapeutic synergies evolve as developers of soft-tissue augmentation systems strive to achieve similar effect and elegance. The high degree of efficacy and safety in the use of botulinum toxins in cosmetic dermatology has produced a great level of satisfaction in patients and physicians alike.

CHAPTER 257

Hair Transplantation and Alopecia Reduction

Walter P. Unger
Robin H. Unger
Mark Unger

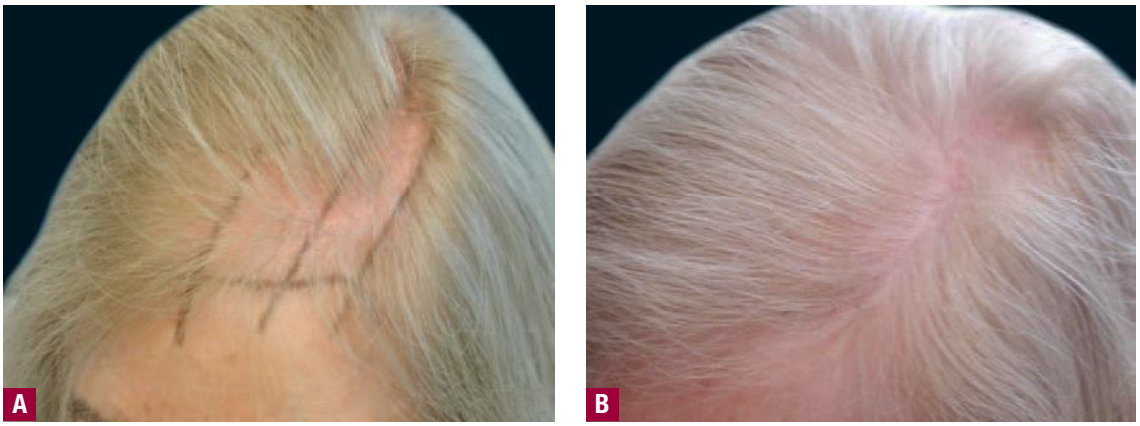
BASIC PRINCIPLES

So that the complexities of modern hair restoration surgery can be understood and put into perspective, a number of basic concepts are first summarized.

Although the surgical options for repair of all types of alopecia can include graft hair transplantation, alopecia reduction, and placement of transposition flaps, almost all of the patients seen for hair restoration surgery have either male pattern baldness (MPB) or female pattern hair loss (FPHL) (see Chap. 86). Almost all are treated with graft hair transplantation, and almost all of the latter are transplanted exclusively with single follicular unit (FU) grafts. [See definition immediately below (Fig. 257-1)]. Follicular unit transplantation (FUT) for MPB and FPHL is the main focus of this chapter.

Hairs emerge from the scalp as single hairs or, far more often, in small groupings of two, three, and less commonly four or five closely associated hairs. These follicular groups or FUs have become the basic building blocks of most modern hair transplantation (see Fig. 257-1). In FUT, the FUs are removed from the permanently hair-bearing rim

◀ **FIGURE 257-1** A relatively small number of single hairs emerge from the scalp. Most often, hairs grow in small groupings of two to five hairs, as shown in the photograph. These groupings are referred to as *follicular groups* or, more commonly, *follicular units*.



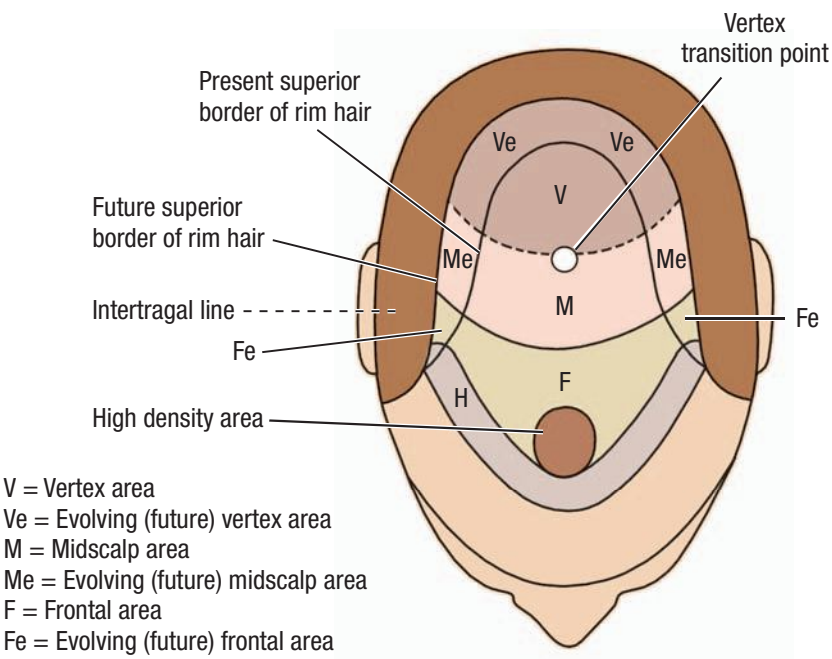
▲ **FIGURE 257-2** **A.** A 61-year-old female patient before hair transplantation with the recipient area outlined in black crayon indicating three zones arranged in order of treatment priority: (1) a part-line corridor on the patient's left side going further posteriorly than the other two zones, (2) an adjacent mid-line frontal zone, and (3) a zone further to the patient's right side. **B.** The same patient with the hair parted in a comparable fashion to that shown in **A** 7 months after treatment with 1118 follicular units.

hair (the donor area) and inserted into small incisions made in the areas of hair loss (the recipient areas). The major advantage of FUT is that one surgery can be performed in an area that is alopecic or destined to become alopecic and it will look essentially natural.

Both MPB and FPHL are intermittently progressive, and even the hair from the "permanent" donor rim becomes less dense throughout the individual's complete lifetime. Thus, a long-term "master plan" that anticipates progression of MPB/FPHL is mandatory. Although minoxidil or finasteride can arrest or even partially reverse MPB and FPHL in some patients—and trial treatment with these agents is therefore always encouraged—there is no scientific support for the assumption of a *permanent* effect of these drugs on either MPB or FPHL.[1,2] In addition, because a completely accurate prognosis is impossible, one must ideally leave a reserve in the donor region for any unanticipated areas of MPB as well as thinning of the transplanted hair.

Most female patients will not have sufficient donor areas of good density to adequately treat all of the affected areas. Thus, for most women the goal is limited to the transplantation of primarily the cosmetically most important area, usually the frontal area (or less often the vertex whorl area) and a 5- to 6-cm-wide antero-posterior corridor through which the patient's hair normally parts (Fig. 257-2). The hair in these thickened areas is styled in such a way as to camouflage the untreated areas. Despite a widespread belief that most women are not candidates for hair restoration surgery, the authors have found the opposite to be true.[8]

Transplantation of the areas of MPB in a large majority of men should be conceptualized as involving four areas: (1) a "frontal" area extending from the intended hairline to a coronal line drawn perpendicularly from the tragus bilaterally; (2) a "mid-scalp" area extending from the posterior border of the frontal area to a point at which the caudal scalp changes its orientation from more or less parallel to the ground to more or less vertical to the ground. This point in the mid-line is referred to as the *vertex transition point*; (3) a "vertex" area, which consists of the remainder of the alopecic regions; and finally (4) the evolving areas of alopecia adjacent to each of the aforementioned three major areas. Evolving areas of hair loss are defined as areas that have hair at the time the physician first sees the patient but from which he or she can reasonably anticipate hair will be lost with the passage of time (Fig. 257-3, see eFig. 257-3.1 in on-line edition, Fig. 257-4). Most commonly, each transplant session will



▲ **FIGURE 257-3** A schematic showing frontal, mid-scalp, and vertex areas as well as evolving areas of male pattern baldness (MPB) in a patient with type VI MPB. Ideally, each of the three major areas is treated at the same time as the evolving areas of MPB lateral to them. Typically, only one major area and the adjacent evolving area are treated during each session, although touch-up thickening of previously transplanted sites may also be carried out at the same time.

◀ **FIGURE 257-4** **A.** A 67-year-old patient with type VII male pattern baldness (MPB) and a relatively sparse donor area, before treatment. The black crayon lines delineate the areas to be treated. Reconstruction of the supratemporal "humps" will allow the new hairline to be positioned more superiorly than usual, which decreases the antero-posterior length of the frontal area and results in the consumption of fewer grafts for that zone. It also can run parallel to the ground when viewed laterally, despite its more superior positioning. **B.** A side view of the same patient 11 months after the second of two surgeries with low follicular units (FU)/cm^2 density [one session addressing the frontal area and one the area further posteriorly, using a total of 3211 FUs]. The advantages of re-creating supratemporal humps and creating a more superior hairline than usual are more obvious for patients who have (or are destined to develop) type VII MPB than for patients who have or will likely develop less severe MPB, such as the one shown in eFig. 257-3.1 in on-line edition. **C.** A frontal view of the same patient. A third session in which 1386 FUs were transplanted posteriorly to those placed during the second session was subsequently carried out just after this photograph was taken.

treat primarily one of the three major areas, plus the adjacent evolving areas. There are variations, however, depending on the size of the recipient area.

In his study of 328 males age 65 years or older Unger delineated an area within the zone of apparently permanent rim hair that contained eight or more hairs per 4-mm circle. He called this area the *safe donor area*[5] (Fig. 257-5). In the authors' experience, very few individuals can be expected to have fewer than two or three 8- to 10-mm-wide strips available from a safe donor area. In practice, hair restoration surgeons usually excise only four or five 10-mm strips (or the equivalent in more or fewer sessions) over the course of treating most patients. Each of these strips can be expected to produce 1500 to 2750 or more FUs, depending on the density of the donor hair area.

PATIENT SELECTION[9]

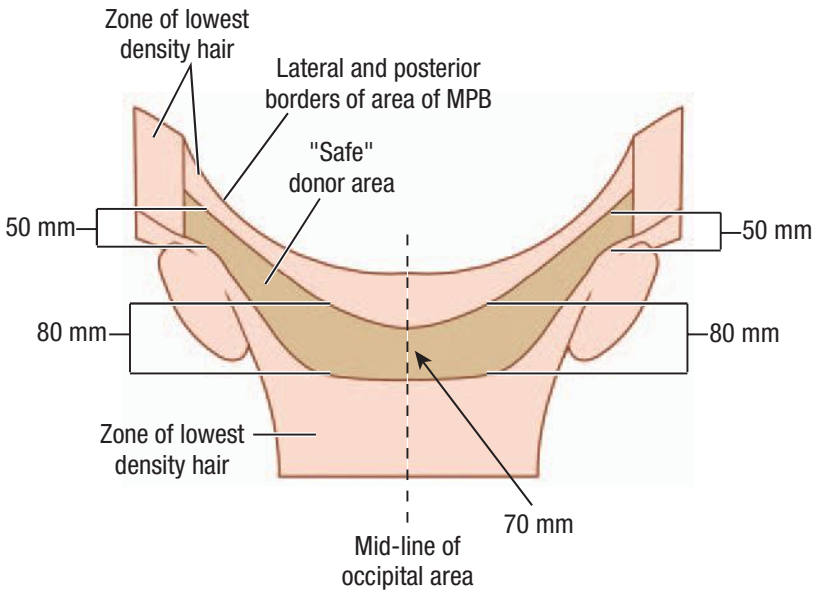
Hair transplantation has become a widely available modality for the treatment of alopecia, and although many prospective patients are candidates for the procedure, there are some guidelines that should be used in assessing patients during the initial consultation. The first step by the hair restoration surgeon is to eliminate the possibility that the hair loss is temporary or medically treatable. A comprehensive discussion of this topic is presented in Chap. 86. If the alopecia is determined to be permanent and without available medical treatment, a thorough history is taken and a thorough examination of the hair and scalp is conducted. It is important to assess not only the current but also the long-term donor-recipient ratio—the amount of hair available for transplantation from the safe donor area compared with the size of the area that ultimately will be affected by alopecia. The physician's predictive abilities depend on experience, available history of familial MPB or FPHL, and most importantly the patient's age.

The authors do not follow any strict rules on patient selection with respect to stage of hair loss or age. However, it is advisable to encourage younger patients (under the age of 25 years) to try medical treatment to delay the progression of MPB before beginning surgical treatment. In general, the younger the patient, the more conservative the approach, and as also noted earlier in Basic Principles, enough hair should be preserved in the safe donor area to provide for at least one or two future transplant sessions to treat areas of unexpected loss.

Box 257-1 lists the characteristics of the best hair transplant candidates. The patient need not have all of these characteristics to achieve a satisfactory result, but each one helps to improve it (Fig. 257-6; see eFig. 257-6.1 in on-line edition). In many instances, only a few of the ideal characteristics are present, and the surgical plan for each patient must take any limitations into consideration. In women, for example, the amount of "permanent" donor hair is usually much smaller than in a typical male patient with MPB. However, FPHL usually does not result in complete alopecia as does MPB, and women generally have many more styling options. In the authors' experience, hair transplant surgery is a very viable option for the majority of patients with MPB and FPHL, provided that the goals are commensurate with the patient's hair and financial resources.

RISKS AND PRECAUTIONS

Before surgical treatment is begun, the patient's physician is contacted to discuss any areas of significant concern revealed by the patient's medical history. For safety, the operating room must have all medications and equipment needed for basic monitoring as well as advanced life support. The authors prefer to have a



▲ **FIGURE 257-5** Unger's safe donor area for 80 percent of patients under the age of 80 years, as determined from studies of 328 men aged 65 years or older.[5] MPB = male pattern baldness.

Box 257-1

Characteristics of the Best Hair Transplantation Candidates

- A high density of hair in the safe donor area (defined as more than 80 hairs/cm^2).
- A mixture of finer-caliber hair for the hairline zone and coarser hair to help create density; if the diameter of an average hair is increased by only 0.01 mm, hair bulk will increase by 36 percent, and therefore coverage will increase by 36 percent.
- Minimal contrast between the skin and the hair color.
- Some wave, curl, and/or frizz.
- Existing hair in the recipient area, which may or may not be permanent but helps with camouflage during the postoperative period.
- *Reasonable* objectives for coverage and hair density in light of all the preceding.

board-certified anesthesiologist present during treatment of patients with significant and/or new-onset cardiovascular conditions, seizure disorders, certain respiratory conditions, and other potentially serious underlying health risks.

There are very few potential complications during hair restoration surgery. Box 257-2 describes those of which the surgeon needs to be most aware and some preventive measures.

PATIENT POSITIONING

During the removal of the donor strip, the patient is placed in a prone position, with the head in a special prone pillow that allows comfortable breathing while face down (see eFig. 257-6.2 in on-line edition). During the creation of the recipient sites and insertion of the grafts, patients are usually in a semi-supine position, except occasionally during surgery on the inferior portion of the vertex recipient area. In the latter circumstance, if the direction of the hair should be posterior or inferior, making of the sites and insertion of grafts is facilitated by putting the patient back into a prone position employing a prone pillow.

EQUIPMENT

The equipment required for hair restoration surgery is listed in Box 257-3.

ANESTHESIA[11]

At least 20 minutes before surgery begins, patients typically are given a hydrocodone/acetaminophen tablet and 20 mg of oral diazepam (Valium). An anesthetic field block is first created, using 30-gauge needles and 2 percent lidocaine with 1:100,000 epinephrine, which is added the morning of surgery to avoid the burning sensation associated with the acidic pH of stock solutions. Wheals of anesthesia are produced along the inferior edge of the donor area at intervals of approximately 3 cm. The gaps are then gradually closed by infiltrating laterally in both directions, inserting the needle through the already anesthetized regions. Thus the patient feels fewer than half the total number of injections. A solution of 1:50,000 epinephrine is then infiltrated into the donor area. Patients who have had previous surgeries occasionally develop aberrant nerve pathways that can escape the inferior field block, and any areas in which the individual is able to feel the epinephrine injections are further anesthetized, usually with lidocaine 2 percent, or sometimes 3 percent with 1:50,000 epinephrine if the patient is especially difficult to anesthetize. Normal saline 10 mL to 40 mL is injected in advance of the donor tissue excision to provide maximum turgor. The

◀ **FIGURE 257-6** **A.** Patient before transplantation. **B.** One year after one follicular unit transplantation (FUT) session (1947 FUs). This unusually dense result with FUT is mostly due to the patient's relatively high-caliber and wavy hair.

Box 257-2

Potential Complications of Hair Restoration Surgery

- Lidocaine toxicity: To minimize the risk of seizure, 20 mg of diazepam is administered to raise the minimal convulsive dose, and the lidocaine is injected intermittently and superficially.
- Syncope: The risk of syncope is minimized by controlling pain and anxiety, keeping the patient in a prone or supine position, and maintaining appropriate hydration and blood glucose levels.
- Intraoperative bleeding: Bleeding is controlled with the use of intradermal epinephrine, manual pressure, and cauterization when appropriate.

Box 257-3

Equipment Required for Hair Restoration Surgery

- Stainless steel bowls for saline and hydrogen peroxide
- Doubled-bladed cutting knife handle
- No. 10 Persona scalpel blades (American Safety Razor, Verona, Virginia)
- Hypodermic needles, 18, 19, and 20 gauge
- 0.5% bupivacaine
- 2% lidocaine with and without 1:100,000 epinephrine
- 4% lidocaine
- Epinephrine 1:1000
- China marker/grease pencil
- Glass Petri dishes
- Hyfrecator and tips
- Needle driver
- Supramid 2-0 CL20, and 3-0 sutures
- No. 15 blade
- Double-sided razor blades
- Razor blade holder
- Clear plastic cutting boards
- Mantis microscope with underlighting (Vision Engineering, Connecticut)
- Curved Metzenbaum scissors
- 1 small curved surgical scissors
- 1 small straight iris scissors
- Aluminum rattail comb
- 4 × 8 and 4 × 4 gauze
- Kerlix dressing (Kendall Co., Basingstoke, United Kingdom)
- 7.5 × 10 cm Telfa pads
- 2 mirrors
- Lepaw graft coolers (Ellis Instruments, New Jersey)
- Ceramic escargot dish
- Nu-gauze (Johnson and Johnson Medical Ltd., Gargrave, Skipton, United Kingdom)
- Spray bottle with saline
- No. 2 jeweler's forceps
- No. 5 planting jeweler's forceps
- 2 toothed curved forceps
- Straight Adson forceps
- Smoke evacuation system

latter helps to minimize bending of the follicles as blade pressure is applied and thus limits FU transection.

The recipient area field block is produced in a similar manner (see eFig. 257-6.3 in on-line edition); however, 3 percent or 4 percent lidocaine with 1:50,000 epinephrine is sometimes needed for "hot spots." A 1:50,000 epinephrine solution is injected intermittently and superficially into the recipient area to provide better hemostasis during the staged incising of the recipient sites.

TECHNIQUE

Recipient Area Design[9]

On the morning of the surgery, a grease pencil is used to outline the treatment area that has already been largely decided upon during the prior consultation(s).

The frontal recipient area is designed by first drawing in the proposed hairline, whose mid-line anterior-most point is as superior as is acceptable to the patient but always lies within the area in which the vertical forehead is changing into the essentially horizontal caudal scalp. Then the lateral borders are determined by outlining the supratemporal "humps"—semi-hemispheric areas that are superior to the temporal areas in type VI MPB and in all less severe types of MPB. These "humps" may or may not still have existing hair (see eFig. 257-3.1 in on-line edition and Fig. 257-4).

The posterior border of the frontal area as well as the mid-scalp area is completed in an arc that will help create a natural shape for the remaining area of alopecia in the event that the patient decides not to transplant any further posteriorly—or does not have sufficient donor hair to do so.

Donor Area Determination[5]

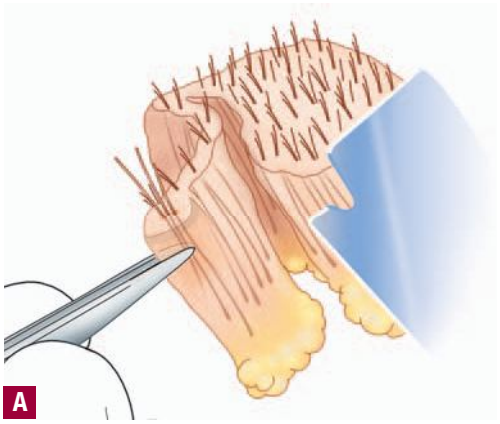
Choosing the optimal location and width of the donor strip is one of the most important decisions that is made in the course of hair transplanting. The authors typically choose a donor area that lies in the middle of the densest zone of the rim hair. Each subsequent harvest will remove donor hair from just superior and just inferior to the scar created in the previous surgery. The midway position is most logical, because hair is progressively lost from both the superior and inferior borders of the rim hair in MPB, and this position provides the greatest certainty that the hair removed is truly permanent. To determine this location, it is sometimes helpful to wet the hair to identify the superior and inferior margins of the current areas of thinning. The donor area extends into the temporal region in many males but remains posterior to the ears in females. The hair in an 8- to 12-mm-wide zone is clipped to approximately 3 mm in length, and the area is cleaned with alcohol and then a povidone-iodine (Betadine) solution.

Donor Site Excision[5]

Before the excision is started, the anesthesia is checked to ensure a complete field block. Laxity of the scalp is assessed to determine the appropriate width for the excision. The angle of the hair in the donor area also has to be taken into consideration when deciding on the width between the blades, because an acute hair angle can cause the resultant strip to be much wider than the actual distance between the blades. The authors always take a slightly narrower strip than the examination might suggest would be possible. This allows for a margin of error in the estimates. Our strips are typically 8 to 10 mm wide. As indicated earlier in Anesthesia, before starting the excision, the area is tumesced with normal saline. We use a double-bladed scalpel, which is angled to mimic the exit angle of the existing hair as the incisions are made. The incision begins and ends approximately 2 cm medial to the ends of the donor area that was mapped out previously.

The entire strip is usually removed in three sections to provide greater control of bleeding. Any vessels that are bleeding more than average are cauterized with a unipolar hyfrecator. Hair that has fallen into the wound is removed, and a running single-layer closure with a 2-0 or 3-0 thread is carried out.

Follicular unit extraction (FUE) is a new technique in which individual FUs are excised directly from the donor area rather than from a strip.[13,14] Typically, a 0.7-mm to 1.2-mm circular incision is created with a trephine. The objective is



◀ **FIGURE 257-7 A.** The excised donor strip is initially sectioned into slices that are one follicular unit (FU) in width, much as one cuts a loaf of bread into slices. **B.** Pear-shaped, chubby, one-haired, two-haired, three-haired, and four-haired FU grafts. Note the intact sebaceous glands and the fat pads below the dermal papillae. (Used with permission from Dr. David Seager.)

to encircle the FU and to incise only as deeply as the reticular dermis. The rest of the FU is teased out of its site with a combination of tension and (1) small needle punctures intended to free the FU from its surrounding tissue and/or (2) pressure applied with a dull-edged trephine.

It is likely that donor area harvesting will evolve into a hybrid of strip harvesting plus FUE from scalp areas of lesser hair density and possibly even from other hair-bearing areas of the body.

Graft Preparation[15]

The preparation of grafts is accomplished using stereoscopic microscopes or magnifying loupes or glasses. After the removal of the donor strip, the technicians begin "slivering the loaf"—a term used to describe the manner in which slices that are one FU in width are carefully produced from the strip, much as one cuts bread into slices (Fig. 257-7A). These slices are 4 to 10 FUs in length, depending on the density of hair in the donor area and the width of excision. The slices are then further divided into the individual FUs. The ideal FU has had most of its epidermis removed and is somewhat tear-shaped, growing progressively wider from an almost absent epidermis to just beneath the hair bulb, where a short tag of subcutaneous tissue is left in place (Fig. 257-7B). The donor tissue is kept moist at all times, and the FUs produced are quickly transferred to a sterilized escargot dish that has wells filled with normal saline and sits on an ice-filled Pyrex container (see eFig. 257-7.1 in on-line edition). The grafts are sorted into FUs with different numbers of hairs and "follicular families" that consist of two FUs that are closer to each other than usual and can be inserted into a small needle hole. Each type of graft is put into an escargot dish well, and the well is labeled so that when the planter requires, for example, a one- or two-hair FU or a three-hair FU, he or she can immediately find one by going to the appropriate well.

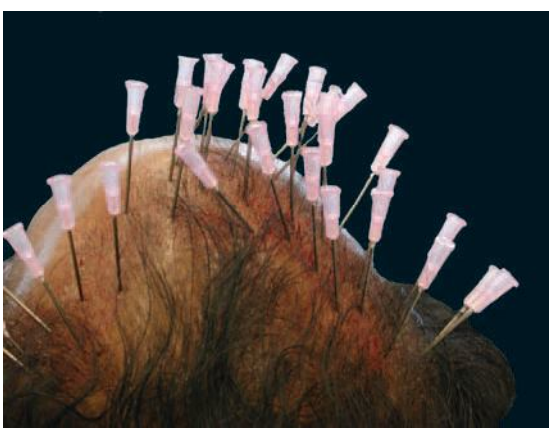
Recipient Site Creation[16]

Recipient sites are created using primarily 18- to 20-gauge hypodermic needles or small blades cut with a special tool to match the size of the grafts. The incisions are made at the same angle and in the same direction as the persisting terminal or vellus hairs in the area. Much of the art of hair transplanting lies in the ability of the surgeon to do this successfully, because both direction and angle vary considerably from patient to patient as well as from one area to another on a given patient's scalp (Fig. 257-8). Moreover, if the surgeon fails to do this accurately, any existing hair in the recipient area can be lethally damaged. For both these reasons, most practitioners prefer to create the sites themselves instead of delegating this task to a technician. Currently, the authors prefer to use a graft density of 20 to 30 FU/cm^2, because virtually all studies on hair survival to date have shown what we consider to be an unacceptable decrease in hair survival rate when a higher FU density (dense packing) is used[17] especially when total recipient site length exceeds 3.0 cm/cm^2. The production of very high hair density should nearly always be limited to small cosmetically strategic regions of the recipient area, including most often an egg-shaped area in the anterior mid-line frontal region (see Fig. 257-3) that creates the impression of high density in the entire frontal area despite its limited size. In that area, the authors prefer to create density by using follicular families (Table 257-1) and three- and four-hair FU grafts in the first surgery and treating the area a second time, while concomitantly treating the mid-scalp if more density is required.

To determine the size of graft site required, several grafts are tested in various locations, and the needle or blade is then adjusted accordingly.

Repair Surgery[18]

The recipient areas of many patients who have the problems associated with older techniques and/or poor planning can be greatly improved with modern hair transplanting methods, primarily by placing FUs anterior to as well as between larger old grafts (Fig. 257-9). Grafts that have been placed too far an-



◀ **FIGURE 257-8** Although various general directions and angles of hairs in different areas of the scalp have been described, none of these generalities applies to all patients. Hair directions and angles can also change dramatically in relatively small areas, as indicated in this photograph showing needles inserted at the angles and directions of hairs at these locations. The surgeon should go very slowly and follow what he or she sees rather than any general rule.

TABLE 257-1
Graft Terminology

Graft Type	No. of Hairs	No. of FUs	Recipient Site	Cut to Size or Cut to Number of Hairs
Micrografts				
Micrograft[15] (general term)	1–4	1 or fewer	Needle/micro-slit	Number of hairs[1]
Follicular unit (FU)[15] (specific term)	1–4	1	Needle/micro-slit	Number of hairs[1]
Follicular family[3]	5–6	2	Needle/micro-slit	Number of hairs[2]
Multi-FU Grafts				
Micro-Slit Grafts[3]				
Double FU	3–5	2	Slit	Number of hairs (FUs)
Triple FU	5–8	3	Slit	Number of hairs (FUs)
Quadruple FU	6–12	4	Slit	Number of hairs (FUs)
Traditional Slit Grafts[3]				
Small slit graft	3–5	~ 2	Slit	Size
Medium slit graft	5–8	~ 3	Slit	Size
Large slit graft	6–12	~ 4	Slit	Size
Slot Grafts[4]				
Small slot graft	6–8	~ 4	Slot	Size
Medium slot graft	8–12	~ 6	Slot	Size
Large slot graft	10–16+	~ 8	Slot	Size
Round Grafts[5]				
Small round graft	5–8	2–3	Punch	Size
Medium round graft	8–14	4–5	Punch	Size
Large round graft (includes standard punch graft)	14–30+	6–15+	Punch	Size

teriorly must be excised either individually or by using an en-bloc elliptical excision. The excision of all or a portion of larger pluggy-looking grafts may also be useful in minimizing "plugginess" (see eFig. 257-9.1 in on-line edition) while providing additional hair for transplanting elsewhere in the recipient area.

Graft Insertion

After the recipient sites have been created, the surgeon reviews with the assistants the locations where the one- to four-hair and follicular family grafts should be placed. Then two or three technicians begin inserting them. A group of five to seven grafts is removed from the saline-filled wells and placed on the hand or finger, and then each graft is placed in its site. A skilled technician determines the angle and direction of the recipient site and then slides the graft into place using a very light touch by following the perceived angle and direction. The recipient area is kept clean by regularly use of a mixture of saline (75 percent) and hydrogen peroxide (25 percent). The grafts are left slightly elevated to help in identifying sites that have not yet been filled. At the end of the procedure, grafts are re-positioned level with the epidermis or left slightly elevated—but never depressed, because this can cause noticeable pitting.

SIDE EFFECTS AND COMPLICATIONS[19]

The possible side effects and complications of hair restoration surgery are listed in Box 257-4. Some of these side effects and complications require additional discussion, as follows:.

Severe postoperative edema can be unsightly and can interfere with healing of the donor area. This risk is minimized with the use of systemic and intralesional corticosteroids, proper postoperative patient positioning, and application of ice compresses.

Infection is minimized by the use of perioperative antibiotics given prophylactically.

Occasionally donor area bleeding occurs in the first few days postoperatively, but it usually resolves with firmly applied pressure. In very rare cases, an extra suture may be needed.

Specific measures can be taken that will minimize the likelihood of wide scars in the donor area. The wound is best closed with the absolute minimum of tension. Harvesting a strip that is 1 to 3 mm narrower than would otherwise be preferred, taking precautions to control postoperative edema, and ensuring proper postoperative care (see Monitoring and Follow-up) facilitate rapid healing. Although these measures prevent wide scars in the donor area in almost all patients (scars are usually 0.2 to 1.5 mm wide), intrinsic poor wound healing characteristics and/or severe scarring from prior surgery can still result in wider than average scars.

Poor graft survival and hair growth is probably entirely avoidable and has never occurred in the authors' experience; however, it has been observed in patients seen for repair procedures.

Telogen/anagen postoperative hair loss may occur in hair-bearing areas in the recipient or donor areas or both. It is presumably due to interruption of blood supply and is always temporary. Approximately 10 percent to 20 percent of male patients and 50 percent of female patients experience at least some degree of this type of hair loss.

MONITORING AND FOLLOW-UP[20]

All patients are seen the day after surgery for bandage removal (if a bandage was used) and for any graft repositioning that occasionally may be necessary. The hair and scalp are thoroughly washed by a technician, and postoperative instructions are reviewed. Minoxidil 3.5 percent (made by mixing 2 percent and 5 percent minoxidil solutions) is applied to the recipient area and sometimes also to the donor area. A thin layer of Aquagel (Parker Laboratories Inc., Fairfield, New Jersey) is then applied to the recipient and donor areas to help maintain moisture and promote healing. All patients are seen 7 to 10 days postoperatively so that the surgical areas can be checked and the sutures removed. Occasionally patients are also seen 4 or 5 days after surgery to be certain they are healing appropriately and following the instructions properly.

A follow-up appointment is generally booked 6 to 12 months after surgery to assess the results and determine the next course of action. The most frequent reason for earlier postoperative visits is reassurance.

The application of ice packs and head elevation should continue for at least the first 3 to 5 days postoperatively if significant edema develops.

From day 2 postoperatively until the sutures are removed, patients should

▲ **FIGURE 257-9** **A.** This 56-year-old man had undergone hair transplanting 15 years before coming for treatment. He had fine reddish to blonde hair. The transplanted area was moderately pluggy-looking and would have appeared much worse had his hair not been so fine and relatively light-colored. The density in the transplanted area was also relatively low. In addition, his male pattern baldness (MPB) was obviously extending further laterally, and he had lost all of the hair posterior to the transplanted zone. He was basically left with a pluggy-looking, unsatisfactory, isolated frontal forelock, as shown in the photograph. We designed lateral "humps" for completion of the frontal third of the area of MPB and a new hairline zone anterior to the old one. The black crayon line delineates these objectives. **B.** A mixture of different types of grafts was used for the corrective procedure. The follicular units (FUs) were used to create the new humps and the bulk of the hairline zone, as well as to fill small spaces between the old round grafts in the hairline zone. The most posterior border of the newly transplanted area was also treated with a zone of FUs. Small round grafts were inserted into larger alopecic spaces between some of the round grafts in the old hairline zone. Double FUs were used primarily just posterior to previous transplantings (Table 257-1). **C.** The new frontal hairline constructed primarily with FUs. As can be seen, the spaces between some of the old round grafts that contained relatively dense hair were to be filled with additional round grafts. Because of the fine texture of the hair and the advantageous coloring, we felt we could get additional density by filling in the spaces between these round grafts with new 2-mm round grafts without sacrificing naturalness. **D.** Nine months after the first repair session, in which 1270 FUs, 105 double FUs, and twenty-one 2-mm^2 grafts were placed. Additional refinement of the hairline zone was carried out at the same time as a second repair session (using exclusively FUs) to transplant the mid-scalp shortly after this photograph was taken.

soak and massage their heads twice daily and apply the 3.5 percent minoxidil solution and then Aquagel. Application of minoxidil is continued for another 4 weeks to promote vasodilation in the surgical area, which theoretically may improve healing; reduce the possibility of any telogen/anagen effluvium; and accelerate re-growth of the transplanted hairs.

It is recommended that patients avoid any significant physical activity for 1 week after surgery and heavy weight lifting for 2 weeks. Pain medication is rarely needed after the first 1 to 2 days; however, it is provided for those with unusually low pain thresholds. The authors believe there is no reason for patients to experience discomfort and recognize that individuals respond very differently to pain and medication.

ALOPECIA REDUCTION[21]

Alopecia reduction (AR), or scalp reduction, can be defined as the excision of an area of alopecia or future alopecia (see eFig. 257-9.1 in on-line edition). The larger the area that can be removed, the smaller the remaining area of alopecia, so that fewer grafts will be required to produce the same hair density. A variety of AR patterns have been described, but the most common patterns used are the ellipse, the inverted Y pattern, and the "lazy-S" shape. The inverted Y pattern should be used if one anticipates insufficient donor tissue to transplant the entire alopecic area even after AR. This design avoids a scar in areas that cannot later be covered with transplanted hair.

Technique

If the pattern is an ellipse, a variant of an ellipse, or a lazy S, an incision is made down to and through the galea aponeurotica along one side of its entire length, usually in a staged fashion. Care is taken to angle the blade so as to not injure any adjacent follicles. If previously transplanted grafts are nearby, a 2-mm margin of safety is observed. Mayo scissors are used to begin the undermin-

Box 257-4

Side Effects and Complications of Hair Transplantation Surgery

- Temporary hypoesthesia of the scalp in either the recipient or donor area (100%)
- Telogen/anagen effluvium in either the recipient or donor area (10% to 50%)
- Postoperative bleeding (less than 0.02%)
- Infection in donor or recipient area (less than 0.01%)
- Excessive postoperative edema (10% to 15%)
- Nausea and vomiting (less than 1%)
- Temporary headache (less than 5%)
- Permanent hypoesthesia in small areas (less than 1%)
- Pruritus (0.1%)
- Pitting or cobblestoning around the grafts (rare with proper technique)
- Poor hair growth (*extremely* rare with proper technique—see text)
- Wide donor area scars (rarely occurs with proper technique)
- Postoperative syncope (less than 0.1%)
- Ingrown hairs (less than 2%)
- Sterile folliculitis (less than 1%)
- Bacterial folliculitis (less than 0.1%)
- Hiccups (less than 0.1%)
- Keloid formation (extremely rare without prior history)
- Neuroma (less than 0.01%)
- Persisting scalp pain (less than 0.001%)
- Arterio-venous fistula formation (0.005%)
- Osteomyelitis (one case reported)
- Septicemia (one case reported)

Note: Figures in parentheses represent the authors' experience.

ing between the periosteum and galea aponeurotica. It is then completed to at least 10 cm or more on either side by blunt finger dissection.

The amount of redundant scalp tissue is estimated by overlapping the tissues, and perpendicular incisions are made through the top flap, stopping at the points at which the flaps meet. The perpendicular cuts are then joined and the excess tissue is thereby removed.

Complications

Complications of AR include postoperative bleeding, infection, nerve damage, persistent hair thinning or loss in the fringe areas, disorientation of hair direction, and poor scars. All of these occur infrequently or not at all if the procedure is carried out properly. With the passage of time, excision scars may become noticeable as hair is lost in areas through which the scar passes. This is obviously a problem of poor planning rather than an inherently unavoidable complication of the procedure.

ALOPECIA REDUCTION PRECEDED BY SCALP EXTENSION[23]

CONCLUSION

The evolution of hair transplantation over the last 10 to 15 years has resulted in a remarkable increase in the number of patients who are eligible for the procedure and an even more impressive improvement in the naturalness of the results that can be expected. Unfortunately, these new techniques also require far more skill and patience from not only the surgeon but also all of his or her surgical team members. In addition, hair restoration surgeons are not miracle workers, so individuals must be educated as to what they can realistically expect from hair transplantation. When this is done, the reward is nearly always a satisfied and grateful patient. Without such patient education, no matter how fine the result, patient dissatisfaction is almost sure to occur.

in phagocytosis and cell killing disorders, 1348, 1349t, 1362–1370
severe combined, 1358–1360
differential diagnosis in, 151
graft-versus-host disease in, 1359–1360
types of, 1358, 1359t
in X-linked agammaglobulinemia, 1348–1352
in X-linked lymphoproliferative disease, 1354
Immunofluorescence
in bullous pemphigoid, 475f, 475–476, 476f
in cicatricial pemphigoid, 481f, 483
in epidermolysis bullosa, 505, 512
acquisita, 494, 496, 498, 498f
in HIV infection, 1929t
in lichen planus, 252, 252f
in linear IgA dermatosis, 486f, 486–487
in lupus erythematosus, 1530, 1530f
in necrotizing venulitis, 1605
in paraneoplastic pemphigus, 472
in pemphigoid gestationis, 490
in Rocky Mountain spotted fever, 1942
in soft tissue infections, 1727
in varicella-zoster virus infections, 1892
Immunoglobulins
class switching, 322, 1353
complementarity-determining regions of, 320
domains of, 319, 320f
gene rearrangements and diversity, 321
heavy chains of, 319, 320, 320f
hypervariable regions of, 319–320
IgA, 319, 320
in chronic bullous disease of childhood, 486–487
in cicatricial pemphigoid, 481, 483
class switching, 322

in common variable immunodeficiency, 1353
and complement activation, 326
in cryoglobulinemia, 1638
deficiency of, 1353
in dermatitis herpetiformis, 500, 501–502, 502f, 503
and linear IgA dermatosis, 485, 487, 488, 504
eosinophil surface receptors, 287
in erythema elevatum diutinum, 1619
functions of, 320, 321t
in hyper-IgM syndrome, 1353, 1354
in Kawasaki disease, 1628
in linear dermatosis, 358, **485**–490, 496–497, 1375t
in necrotizing vasculitis, 1599
paraproteinemia, 305, 306, 1502, 1619
in pemphigus, 305, 306, 1375t
in polymorphic disease with monoclonal IgA ANCA, 1375t
in psoriasis, 182
in pyoderma gangrenosum, 1502
subclasses of, 320, 321t
in sub-corneal pustular dermatosis, 305, 306
in vasculitis, 1384f
in X-linked agammaglobulinemia, 1352
IgA receptor, 320
IgD, 319, 320
and B cell maturation, 322
class switching, 322
functions of, 320, 321t
hyper-IgD syndrome, 1267t, 1267–1269
in hyper-IgM syndrome, 1353, 1354
IgE, 319, 320, 321
in atopic dermatitis, 148, 150, 151
in bullous pemphigoid, 477, 477f, 478
class switching, 322
in drug hypersensitivity, 358, 361
eosinophil surface receptors, 287
in exfoliative dermatitis, 227, 229
functions of, 321, 321t
in hypereosinophilic syndromes, 309
in hyper-IgE syndrome, 151, 1366f, 1366–1367, 1374t
in hyper-IgM syndrome, 1353, 1354
in urticaria and angioedema, 331, 332–333, 334, 340, 358
contact, 336
IgG, 319, 320–321, 325
in bullous pemphigoid, 475, 475f, 476, 476f, 477, 478, 479
in cicatricial pemphigoid, 483
class switching, 322
in common variable immunodeficiency, 1353
in cryoglobulinemia, 1638
eosinophil surface receptors, 286
in epidermolysis bullosa acquisita, 494, 498, 498f
Fab fragments, 320
Fc portion, 283, 320
in autoimmune disorders, 1510–1511
functions of, 320–321, 321t
in herpesvirus-6 infections, 1866
in hyper-IgM syndrome, 1353, 1354
in Lyme disease, 1798, 1804
in measles, 1851, 1852
in mononucleosis, 1859
in parvovirus B19 infections, 1857
in pemphigoid gestationis, 490, 492
in pemphigus, 461, 461f, 462, 463
paraneoplastic, 471, 472
structure of, 320f
subclasses of, 320, 321t, 331
in urticaria and angioedema, 331, 332, 332f
in viral infections, 1850
in X-linked agammaglobulinemia, 1353
IgM, 319, 320, 325
affinity and avidity of interactions, 320
and B cell maturation, 322
class switching, 322
in common variable immunodeficiency, 1353
in cryoglobulinemia, 1638
deficiency of, 1353
functions of, 320, 321t
in herpesvirus-6 infections, 1866
in hyper-IgM syndrome, 1353–1354
joining (J) chain of, 320
in Lyme disease, 1798, 1804
in measles, 1851, 1852
in mononucleosis, 1859
in parvovirus B19 infections, 1856–1857
in rubella, 1854
in syphilis, 1973
in viral infections, 1850
in X-linked agammaglobulinemia, 1352
light chains of, 319, 320, 320f
structure of, 319–320, 320f
Immunohistochemical tests
in Merkel cell carcinoma, 1088, 1090, 1090t
in Paget disease, 1096
in prenatal diagnosis of skin diseases, 85
of sweat glands, 721, 721f
Immunologic synapse, 131
Immunologically privileged sites, 1511
Immunomodulators
oral, 2217–2223

  nutrition in, 220, 224, 2287
  photo-exacerbated, 825, 825f
  pityriasiform, 221–222
  prognosis and clinical course in, 221, 222
  and psoriasis, 220
  scaling lesions in, 31t
  seborrheic stage in, 220
  treatment of, 223–225, 2121
    complementary and alternative medicine approaches to, 2286–2287
    terbinafine in, 2212, 2213t
Seborrheic keratosis, **1054**–1056
  cryotherapy in, 2331
  laser therapy in, 2273
  Leser-Trélat sign in, 1497–1498
Sebum
  function of, 689
  lipid composition of, 688f, 688–689
  production of, 219
    in acne vulgaris, 692
    embryonic and fetal, 72
    regulation of, 689–690
    in xerosis, 2358
Seckle syndrome, 982t, 1314t
Secondary lymphoid-organ chemokine (SLC), 127, 131, 599
Sedation
  from antihistamines, 2187, 2190
  in drug interactions, 2240t
Sedatives
  abuse of, 922, 924
  pediatric dosage, 952t–953t
Seed corn, 872
Seipin in lipodystrophy, 588
Seizures
  in acute intermittent porphyria, 1251
  in cysticercosis, 2014t
  in tuberous sclerosis, 1328–1329, 1330
Selectins, 281, 282f
  E-selectin, 1590t, 1591, 1594
    and cutaneous lymphocyte antigen, 105, 129–130, 1595–1596
    endothelial expression of, 281, 287
    functions of, 1592t
    in multistep model of leukocyte recruitment, 129–130, 130f
    in necrotizing venulitis, 1600
  L-selectin, 130, 130f, 281, 287, 1591, 1592t
  P-selectin, 1587, 1589, 1590t, 1591, 1595
    endothelial expression of, 281, 287
    functions of, 1592, 1592t
  P-selectin glycoprotein ligand 1, 104–105, 282f, 287, 1387
  in urticaria and angioedema, 341
Selection bias, 3–4
Selenium, 1217
  deficiency of, 1217
    hypopigmentation in, 629, 1217
  food sources of, 1217
  toxicity of, 1217
Selenium sulfide
  in tinea capitis, 1819
  in tinea versicolor, 1830
Self-examination recommendations in dysplastic nevus, 1132
Self-inflicted dermatoses, 914–916
  treatment in, 917
Self-tolerance and autoimmune disorders, 1511–1512
Semmes-Weinstein filaments, 1796
Senear-Usher syndrome, 465
Sensitive skin type, 2364t
  with acne, 2360
  allergic, 2361
  compared to resistant type, 2359–2360
  cosmetic intolerance syndrome in, 2359–2360
  with rosacea, 2360
  with stinging, 2360–2361
Sensory system
  age-related changes in, 967
  and anesthesia as postoperative complication, 2341
  functions of skin in, 57, 58t
  nerves and receptors in, 65f, 65–66, 66f, 895
    anatomy of, 896, 2292, 2292f
    embryonic and fetal development of, 70
    facial, 2292, 2292f
      anesthetic block of, 2298
Sensu stricto, 2025
Sentinel lymph nodes
  in melanoma, 1149, 1151–1153, 1154
  in Merkel cell carcinoma, 1091, 1091f
  in Paget disease, 1096, 1097
  in squamous cell carcinoma, 1035
Sepsis, **1746**–1747
  arthritis in, 213
    in body piercing complications, 890t
  differential diagnosis of, 1747, 1747b
  disseminated intravascular coagulation in, 1747, 1748
  in epidermal necrolysis, 353
  in graft-versus-host disease, 265
  in immunocompromised host, 1746, 1747
  purpura fulminans in, 1383
  severe, 1747
  shock in, **1746**–1747
    in meningococcal infections, 1734, 1735
  treatment in, 1747
  in *Vibrio vulnificus* infections, 1747, 1763, 1764

Septicemia
in melioidosis, 1765
in plague, 1758, 1759
Pseudomonas, 1737–1738, 1739
SERCA2, 61, 68t
